coated, reducing anticoagulation requirements. Because it is available in a wide range of sizes, the Berlin Heart EXCOR VAD provides circulatory support options for pediatric patients ranging from 2.5 kg to adolescents. The Berlin Heart EXCOR was specially designed and developed for pediatric patients. The pump sizes vary between 10 mL and 80 mL. The 10-mL pumps are suitable for neonates and infants with body weight of up to 9 kg (body surface area of 0.2 m^2); the 25-mL and 30-mL pumps can be used in children up to the age of 7 years (weight 30 kg and body surface area of about 0.95 m^2); adult size pumps (50, 60 mL) can be implanted in older children. All Berlin Heart EXCOR cannulas exit the body through the upper abdominal wall (Fig. 30.4 device and cannulas). Survival with the Berlin EXCOR and the MEDOS VADs has been reported at 36% in children from 2 weeks up to age 16 years, including an infant with body surface area less than 0.3 m^2. Diagnosis included fulminant myocarditis, dilated cardiomyopathy, endocardial fibroelastosis, Ebstein anomaly, and status post redo aortic valve replacement. Neurologic complications vary between 25% and 30%.[105,106]

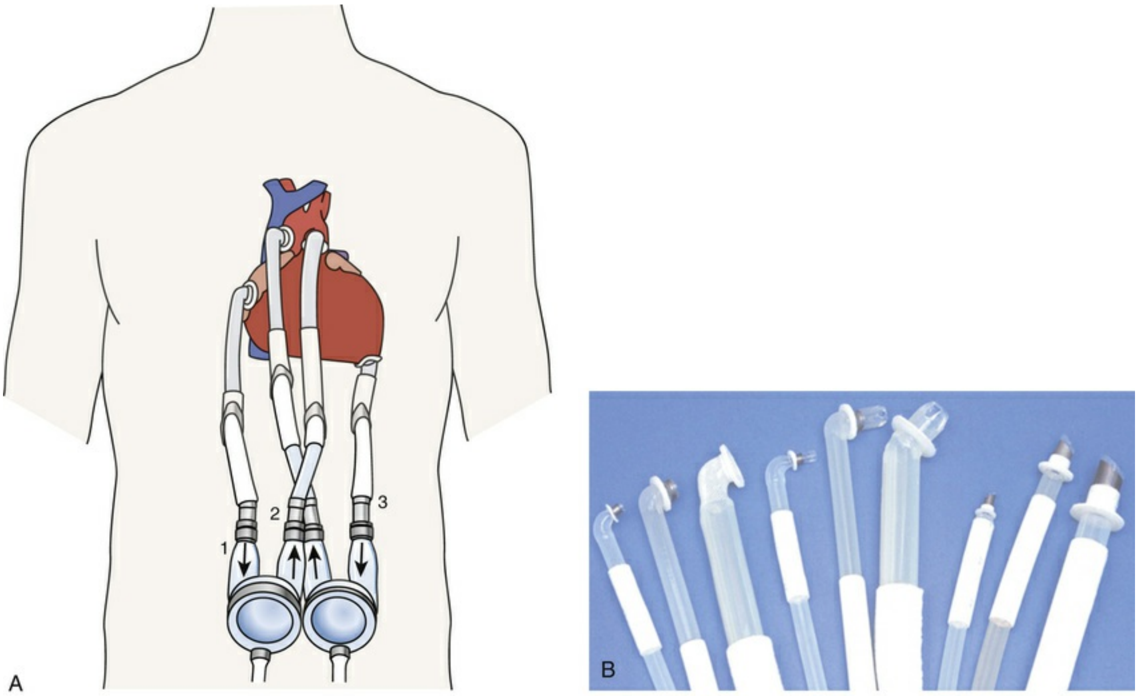

FIG. 30.4 (A) Schematic diagram of the Berlin Heart biventricular assist device showing apical cannulation, which allows better left ventricular unloading and decreased afterload to the right ventricle. 1, Deoxygenated blood flows from the body into the right atrium. Because the right ventricle is unable to pump blood into the lungs, the blood goes into the device. 2, The blood is pumped out from the device into the pulmonary artery. 3, Once the blood is oxygenated in the lungs, it flows into the left atrium. Because the left ventricle is unable to pump, the blood goes into the device. 4, The Berlin Heart pumps blood into the aorta and systemic circulation. (B) Set of cannulas available for the Berlin Heart assist device. The cannulas are available in different diameters, lengths, and tip configurations. (Courtesy Berlin Heart AG, Berlin, Germany.)

The Abiomed BVS 5000 VAD (Abiomed, Inc., Danvers, Massachusetts) was the

first assist device approved by the FDA to be used in postcardiotomy patients. It is a pneumatically driven, pulsatile, extracorporeal pump used in adults for short-term uni- or biventricular support. The BVS 5000 can produce a stroke volume of 80 mL and flows up to 6 L/minute. It has been used in patients with a body surface area (BSA) ≥1.2 m^2, generally as a bridge to recovery in patients who have exhausted all other medical options.

The Thoratec Ventricular Assist System (Thoratec Corp., Berkeley, California) is a pneumatically driven, polyurethane sac enclosed in a plastic housing designed for intermediate and long-term use (weeks to years). The Thoratec VAD has a stroke volume of 65 mL and can be operated at rates up to 100 beats per minutes providing blood flow rates of almost 7 liters/minute. Patients require systemic anticoagulation for the duration of the VAD support. There are two Thoratec VAD systems, one paracorporeal (PVAD) and one implantable (IVAD). The Thoratec Paracorporeal Pneumatic VAD (PVAD) is indicated as a bridge to transplantation or bridge to recovery system. It can provide acute or intermediate uni- or biventricular support. The external position of the pump allows device exchange in cases of malfunction, thrombus, or infection. Furthermore, it can be used in smaller patients who are poor candidates for implantable devices with the smallest reported patient weighing 17 kg (BSA 0.73m^2). In a multicenter study (US and Germany), the Thoratec PVAD was used in 19 children with a mean BSA of 1.09 m^2, (range, 0.73–1.29), a mean age of 10 years (range, 7–14), and a mean weight of 31 kg (range, 17–41).[107] Indications for support were end-stage cardiomyopathy in eight patients, myocarditis in three, end-stage congenital heart disease in seven, and transplant graft failure in one patient. Mean duration of support was 43 days (range, 0–120). Survival through hospital discharge occurred in 8 of 11 (72%) patients with cardiomyopathy or myocarditis; however, only 1 of 7 patients with congenital heart disease survived. Neurologic complications were significant and predominant in the congenital heart disease group. Neurologic complications in these pediatric patients seem to be higher when cannulation is performed in the left atrium versus the left ventricle.[107] The Thoratec IVAD is a smaller, intracorporeal device with the same features as the Thoratec PVAD, except that it is used when longer support is anticipated. The device has been FDA approved since 2004 for circulatory assistance as a bridge to transplant or bridge to recovery. For adults, the pulsatile, axial flow pump, HeartAssist 5 (Reliant Heart, Houston, Texas) is a small LVAD implanted in the pericardial space, which is in clinical trials in the United States.

Continuous Flow VADs

The centrifugal pump that has been most available for use in pediatrics is the BioMedicus centrifugal pump (Medtronic, Eden Prairie, Minnesota) (Fig. 30.5). The BioMedicus centrifugal pump can be utilized for cardiopulmonary bypass, ECLS, or ventricular assistance depending on how the complete circuit is configured. The pump consists of a polycarbonate cone built around several rotator cones. It is magnetically coupled to a driver that controls the revolutions per minute (RPMs). The pump spins at an adjustable rate, generating a vortex continuous flow. This creates negative pressure that forces blood to drain (suctioned) from the venous cannula into the pump and redirects it out the top of the vortex (a tornado effect). The BP-80 and BP-50 models have cone volumes of 80 and 50 mL, respectively, with

maximal flows of 10 L/minute. The centrifugal pump output (flow) is proportional to the rotational speed of the pump (RPM), preload to the pump (patient's intravascular volume), and pump afterload (impedance to outflow). Actual flow is measured with a flow probe on the arterial limb of the circuit, as RPM may not correlate accurately with flow. Heparin-bonded tubing can be used to minimize the need for anticoagulation. Mean arterial pressure is maintained by varying intravascular volume and adjusting RPM on the VAD console. Large negative pressures can be generated, which if excessive can create cavitation and hemolysis. Although the system is designed for univentricular support (LVAD or RVAD), biventricular support (BiVAD) can be obtained with two pumps connected in series.

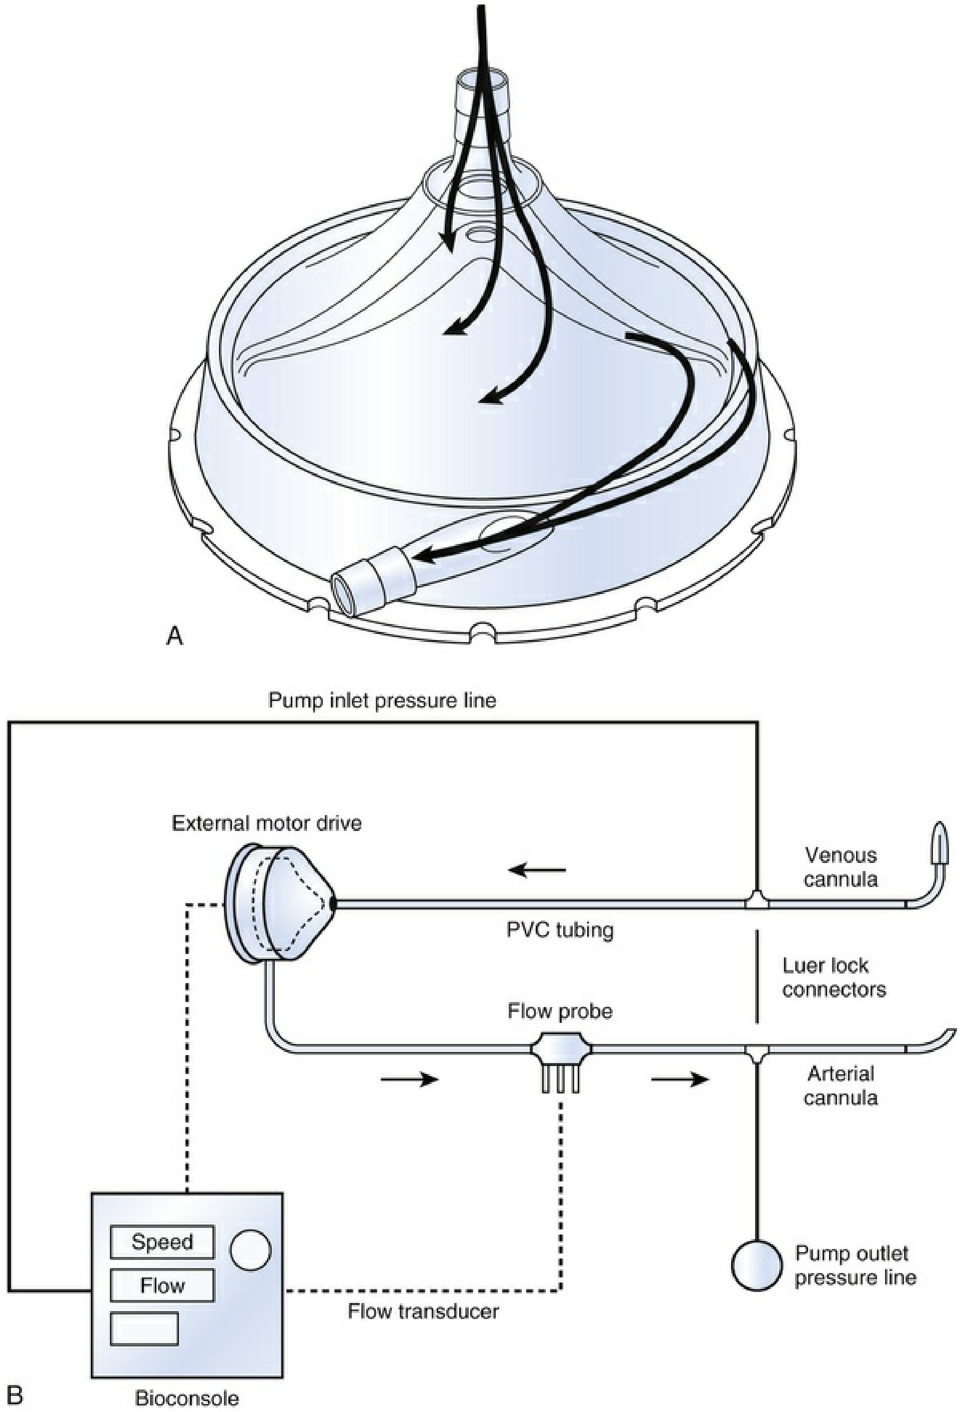

FIG. 30.5 (A) Schematic diagram of the BioMedicus centrifugal pump (Medtronic). Blood enters the cones via the apex of the cone, and the kinetic energy of the spinning cones is transferred to the blood leaving the side port. (B) Centrifugal pump setup. (From Karl TR, Horton SB. Centrifugal pump ventricular assist device in pediatric cardiac surgery. In: Duncan BW, ed. Mechanical Support for Cardiac and Respiratory Failure in Pediatric Patients. New York: Marcel Dekker; 2001.)

The CentriMag VAD (Thoratec Corp., Pleasanton, California) is approved for use as an RVAD for periods of support up to 30 days for patients in cardiogenic shock due to acute right ventricular failure. It belongs to a new class of magnetically levitated devices operating in a bearing-less rotor that floats with a rotating magnetic field. Because of its contact-free environment and absence of seals or valves, this

device minimizes blood trauma, thrombus formation, and hemolysis. It is capable of operating over a range of speeds up to 5500 RPM generating flows up to 10 L/minute. The Thoratec PediMag blood pump, a miniaturized version of the CentriMag, is an extracorporeal circulatory support device providing hemodynamics stabilization for small patients (<10 kg) in need of cardiopulmonary assistance. It is cleared for clinical use up to 6 hours, so it can be used as a short-term solution to support the circulation while longer-term options are considered. It is a magnetically levitated pump and simple to implant. These devices are generally used for short- or intermediate-term support for recovery, conversion to a long-term VAD, or as a bridge to transplant.[108,109]

The HeartMate II (Thoratec Corp., Berkeley, California) is an axial flow rotary pump utilizing blood-immersed mechanical bearings with textured blood-contacting surfaces. The transcutaneous version is totally implantable. The HeartMate II is smaller than the first-generation devices, principally due to the elimination of the sac or reservoir necessary in pulsatile pumps. This device has two cannulas (inflow and outflow) without valves. It has smooth surfaces in the outlet and inlet stators but still requires anticoagulation. Clinical experience shows that the HeartMate II LVAD provides excellent support, with significant improvement in functional capacity. In a multicenter, prospective study, 42% of 133 adult heart transplant candidates supported with HeartMate II underwent transplantation within the 6 months of support, with an overall 6-month survival of 75% and 1-year survival of 68%.[110] More recently, an improved 6-month survival of 86.9% and 3% incidence of device malfunction with a mean duration of support of 6 months has been reported.[111] The FDA has already approved its use as a bridge to transplant therapy and for destination therapy. The HeartMate II has demonstrated great device reliability and significantly reduced device noise. It has low thrombogenicity and low thromboembolic risk, which makes it a good device option for destination therapy. Other examples of continuous flow pumps used predominantly in adults include the HVAD and newly developed mVAD (in clinical trials) (HeartWare Corp., Framingham, Massachusetts), DuraHeart II (Thoratec Corp., Pleasanton, California) RotaFlow (Maquet Holding B.V. & Co., Rastatt, Germany) and TandemHeart System (CardiacAssist, Inc., Pittsburgh, Pennsylvania).

Clinical Indications and Outcomes for Centrifugal Pump Ventricular Assist Devices in Children

Centrifugal VAD pumps have been available since the late 1970s to support neonates and older children with postoperative cardiac failure and preserved lung function (ie, no need for oxygenator).[112] They have been an effective support for infants and children with myocardial failure from a variety of etiologies (ie, acute myocarditis, dilated cardiomyopathy, acute transplant rejection, anomalous left coronary artery from the pulmonary artery, and others).[7,113] Centrifugal pumps are used for short-term support and are in essence mini ECLS circuits without an oxygenator. Advantages of these short-term VAD systems compared with traditional ECLS include lower priming volumes, adequate left (or systemic) ventricular decompression, lower heparin requirements, less hemolysis, ease of transport, and relatively low costs.[114] Centrifugal LVADs require a functional RV to supply preload to the left ventricle drained by the pump. Complications of the centrifugal VAD

system include thrombus formation in the circuit, hemolysis, bleeding (including acquired Von Willebrand disease),[115] and infection.[116] Duncan and colleagues reported the outcomes of 29 pediatric patients supported with the BioMedicus LVAD with a survival of 71% among patients with anomalous origin of the left coronary artery from the pulmonary artery or with cardiomyopathy. In those who underwent heart transplantation after LVAD support, survival was 50% and fewer instances of neurologic complications and hemolysis were seen than in the ECLS group reported in the same study.[48,117] Successful use of the centrifugal LVAD as a bridge to implantable VAD and then to heart transplantation in a patient with single ventricle physiology has been reported.[48,118] Single-center studies have shown little difference in survival rates of patients supported with either a centrifugal or a pulsatile pump.[118,119]

Long-Term Mechanical Support Devices

Mechanical support devices designed for the long-term support of patients have emerged, although devices for neonates and infants are still lacking. Clinical experience with these devices in adults is extensive and includes use in patients with postcardiotomy heart failure, acute myocardial infarction, cardiogenic shock, ischemic cardiomyopathy, and myocarditis. Long-term devices (support >30 days) have been placed in pediatric patients as a bridge to transplantation, bridge to recovery, or destination therapy when permanent circulatory support is needed for patients who are not candidates for heart transplantation.[120-122]

The Heart Assist 5 MicroMed DeBakey VAD (MicroMed Technology, Houston, Texas) was developed in the early 1990s as a result of a collaboration between the National Aeronautics and Space Administration (NASA), Dr. Michael DeBakey, and Dr. George Noon. Since that time, there have been more than 500 implants of this VAD in patients around the world. Design changes have been made to create the HeartAssist 5 (Fig. 30.6A and B), which supports pediatric patients as small as 18 kg. It provides a wide degree of cardiac support with blood flows from 1 to 10 L/min. This is an implantable LVAD, intended for more than 3 months of support, focusing on bridge to transplantation. It represents the first truly miniaturized device, approximately one-tenth the size of other currently marketed pulsatile VADs. The advantages of this device include its small size, relative ease of implant and explant, decreased infection risk, and continuous flow, which unloads the ventricle throughout the cardiac cycle while minimizing stasis and the associated risk of thrombus formation. It can operate up to 8 hours on batteries, thus allowing for better patient mobility. Disadvantages include the rapid impeller speed, which can lead to hemolysis. This device has been granted an FDA humanitarian device exemption and is indicated for use as temporary left-sided MCS as a bridge to cardiac transplantation for pediatric patients between 5 and 16 years of age with BSA >0.7 m^2 and <1.5 m^2 who are in New York Heart Association (NYHA) class IV end-stage heart failure refractory to medical therapy and who are (listed) candidates for cardiac transplantation. An adult version of the HeartAssist 5 is also available. The DeBakey HeartAssist 5 Pediatric VAD is contraindicated in patients suffering from right ventricular failure unresponsive to medical therapy, patients with a primary coagulopathy or platelet disorders, and patients with an allergy or sensitivity to heparin.

(B) HeartAssist 5 with its position in the heart. (C) HeartAssist 5 shown with a US quarter for size comparison. (Courtesy MicroMed Technology, Houston, Texas.)

The Jarvik 2000 (Jarvik Research, Inc., New York, New York) is an intraventricular assist device with a relatively small surface area measuring 1.8 cm in diameter by 5 cm in length. The device usually is implanted into the left ventricular apex via a left thoracotomy, and the outflow graft is placed into the descending aorta. Blood flow ranges from 2 to 7 L/minute and is determined by impeller speed and systemic vascular resistance, with the usual setting at 9000 RPM (range 8000-12,000 RPM). It offers several advantages over pulsatile flow pumps, including smaller size that reduces the risk of infections, simpler implantation, fewer moving parts, absence of valves to direct blood flow, smaller blood-contacting surfaces, and reduced energy requirements that enhance simplicity and durability. The addition of sintered titanium microspheres on its intraventricular blood-contacting surface has decreased the incidence of thrombus formation. This device has an external speed control that can easily be adjusted according to the patient's physiologic needs. The Jarvik 2000 is FDA approved as an investigational device to be used for bridge to transplantation. In Europe, the Jarvik 2000 is certified to be used both as a bridge to transplantation and destination therapy. A pediatric Jarvik 2000 is under investigation.[123]

Total Artificial Heart

Total artificial heart (TAH) devices completely replace the patient's native ventricles and all four cardiac valves and are used as destination therapy. Due to their large size, these devices have limited use in children.[124] CardioWest (SynCardia Systems, Inc.) is the modern version of the Jarvik 7 implanted in 1982. The CardioWest temporary TAH is the only artificial heart in the world. The CardioWest TAH is used as a bridge to heart transplant for eligible patients with severe end-stage biventricular failure. The 70-mL CardioWest TAH is suitable for patients with BSA

≥1.7 m^2; a 50-mL version of the device is under research investigation. The AbioCor Replacement Heart is a new mechanical device that replaces the pumping function of the diseased heart. It is used as destination therapy in patients who are ineligible for heart transplant and have no other suitable treatment options. The AbioCor has been granted FDA approval for the humanitarian device exemption.

Next Generation–Levitated Devices

New generations of devices include centrifugal continuous-flow pumps with an impeller or rotor suspended in the blood flow path using a noncontact bearing design, which uses either magnetic or hydrodynamic levitation. The levitation systems suspend the moving impeller within the blood field without any mechanical contact, thus eliminating frictional wear and reducing heat generation. This feature hopes to promise longer durability and higher reliability with a low incidence of device failure and need for replacement. Usually, magnetic levitation devices are larger owing to the need for complex position sensing and control system. Examples of third-generation devices are the VentrAssist (Ventracor Ltd., Sydney, Australia), Levitronix CentriMag (Thoratec Corporation), DuraHeart (Terumo, Inc., Ann Arbor, Michigan), HVAD (HeartWare Corp., Florida), and EVAHEART LVAS (Sun Medical Technology Research Corporation, Nagano, Japan).[125]

Device Selection

Three factors drive device selection: type of support (cardiopulmonary or cardiac), planned duration of support, and body surface area. Short-term support (less than 14 days) is used for acute myocarditis, graft dysfunction after cardiac transplant, and patients with unknown diagnoses or unknown neurologic status. It is also described for failure to wean from cardiopulmonary bypass. Long-term support (greater than 14 days) is often used in patients with known cardiomyopathy and failure to improve and in some with refractory heart failure and congenital heart disease. Venoarterial extracorporeal membrane oxygenation (ECMO/ECLS) has been successfully used since the mid-1970s and is the most widely available form of short-term biventricular cardiopulmonary support. It is most commonly employed for failure to wean from cardiopulmonary bypass, emergent support after cardiac arrest with failure of medical resuscitation, and early graft failure after cardiac transplantation. Biventricular support with ECMO requires either an opening in the atrial septum or an additional cannula placed in the left heart (pulmonary vein, left atrial appendage, or left atrium). It is important to note that after approximately 2 weeks, the risk of bleeding, thromboembolism, stocking and glove ischemia, and other major complications are common. Another device popular in Europe (FDA approval pending) and used for similar indications as ECLS is the Deltastream DP3 (Medos Medizintechnik AG, Stolberg, Germany).[126] This pump combines the effects of centrifugal and axial pumps. It requires a very small priming volume. These are very short-term devices until one of the following outcomes occur: Pulmonary (not cardiac) recovery leads to the insertion of longer-term cardiac support, cardiopulmonary recovery results in decannulation, or no recovery of either organ system leads to withdrawal of support.

A suggested algorithm for device selection is shown in Fig. 30.7.[127]

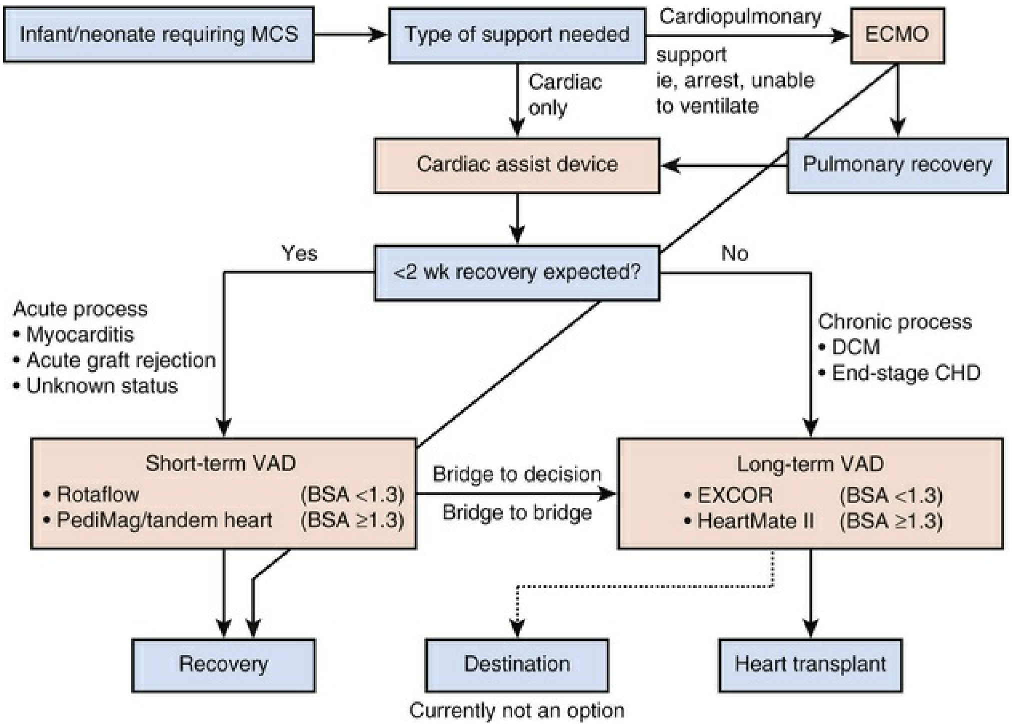

FIG. 30.7 Protocol for device selection; name of the devices used in the figure are authors' preference for each device type. (From Wilmot I, Lorts A, Morales D. Pediatric mechanical circulatory support. Korean J Thorac Cardiovasc Surg. 2013;46:391-401; with permission.)

Patient Selection and Management

In general, the use of MCS in pediatric patients with acute or chronic end-stage heart failure is indicated when conventional medical therapy has failed. Despite listing for heart transplantation, the scarcity of organs usually necessitates consideration of mechanical support. Pediatric VADs are used almost exclusively as either bridge to transplant or bridge to recovery. Unlike in the adult population, the use of MCS as destination therapy is not a primary option in the pediatric population, but it has been reported in patients with Duchenne muscular dystrophy.[128]

Contraindications to the use of VADs in pediatric patients include irreversible end-organ dysfunction and active infection. Also, extreme prematurity, very low birth weight, and certain chromosomal defects are considered contraindications. It is important and often challenging to avoid initiating mechanical support too late. Moderate end-organ dysfunction often improves with MCS, especially renal and hepatic dysfunction.[129] Other considerations include thickness of the ventricular wall, semilunar valve regurgitation, and intracardiac shunts. Thick ventricles (such as those in hypertrophic cardiomyopathy) can prevent proper filling of the VAD, and these patients should be considered on a case-by-case basis.[130] Significant aortic insufficiency (or pulmonary insufficiency) will not permit adequate emptying of the ventricle and often necessitates closure of the aortic valve at the time of VAD implantation. Closure of intracardiac defects will prevent embolization of thrombus or air.[131]

Basic Management of the Ventricular Assist Device Patients

Patients assisted with VADs are not anticoagulated for the first 24 to 48 hours to decrease risk of bleeding. Intravenous unfractionated heparin is then started at 25 units/kg/hour and continued during the time of MCS, keeping anti-Xa levels between 0.35 and 0.7 units/mL. Once postoperative bleeding stops, antiplatelet therapy is started. Achieving optimal anticoagulation levels in children on VAD support remains a significant challenge. Children with ongoing VAD support often have issues with gastrointestinal function, such as feeding intolerance secondary to right heart failure, resulting in erratic absorption of enteral medications. The Edmonton protocol[85] involves a three-drug regimen, namely aspirin, dipyridamole, and either warfarin or enoxaparin depending on patient age. This protocol was used as a guideline in the Berlin EXCOR Investigational Device Exemption (IDE) prospective trial.[106] Despite the guideline, the prevalence of major bleeding was significant: 42% in patients with BSA $<0.7 m^2$ and 50% in patients with BSA 0.7-1.5 m^2. Unfortunately, there was also a significant prevalence of thrombosis, the most concerning of these events being stroke (29% in both cohorts). The occurrence of hemorrhagic and thrombotic complications appeared to be higher than those in the German trial.[104] Further randomized trials are warranted to further evaluate anticoagulation protocols in this patient population. At present, however, the EXCOR device remains the only pediatric VAD that can be used in all age groups. The prevalence of bleeding and stroke is of great concern and exhibits the same challenges that have plagued the use of all extracorporeal technology in critically ill children.

Infection prophylaxis using broad-spectrum antibiotics as well as antifungal drugs is continued for 48 hours after the implantation. Wound care consists of daily dressings using sterile saline. Once the drains are removed, the wound and cannula dressings are changed twice a week and surveillance cultures of the wound and cannula are obtained once a week.

Single-center studies have reported readmission rates after LVAD implantation of between 1.5 and 2.5 per patient-year of support, with an increased rate in the first 6 months after the implant. The leading cause of readmission was bleeding (primarily gastrointestinal), followed by heart failure/arrhythmia and infection.[132,133]

Mechanical Circulatory Support and Single Ventricle

Two general categories of patients with single ventricle physiology may require MCS support: those with prior palliative surgery but without complete separation of the systemic and pulmonary circulation and patients who are post-Fontan. In the first group, inflow is provided from the single ventricle with outflow to the ascending aorta. Pulmonary blood flow is maintained via a systemic-to-pulmonary artery shunt or a bidirectional Glenn shunt. In patients with a failing Fontan, cardiac failure may result from primary ventricular dysfunction producing high Fontan pressures or from failing Fontan physiology (preserved ventricular function but

moderate to severe elevation of pulmonary vascular resistance) yielding chronic elevation of pressures in the Fontan pathway and sequelae of heart failure. In primary ventricular dysfunction and normal PVR, standard ventricle-to-aorta support may be sufficient. However, in the setting of failing Fontan physiology, cannulation choices are more challenging. If elevated pulmonary vascular resistance leads to systemic venous hypertension, then a second VAD may be required to support flow through the pulmonary circulation. In this situation, separation of the two circulations is performed by taking down the Fontan pathway.[134,135]

Some authors do not offer VADs to patients with single ventricle congenital heart disease and opt to support these children with ECLS. Nevertheless, there are several case reports describing the use of VAD support for single ventricle heart failure. The Edmonton group[136] reported the use of VAD support for a 3-year-old with early heart failure following a Fontan operation. The patient's anatomy was revised back to a bidirectional cavopulmonary connection, with initiation of ECMO. Support was later converted to a Berlin Heart EXCOR pediatric device, which was implanted with systemic right ventricular and aortic cannulation. This patient underwent successful heart transplantation after being supported with the EXCOR for 6 months. As the authors state: “the paucity of published reports on VAD support in single ventricle patients precludes firm recommendations regarding surgical management strategy.”

Outcomes

The Berlin Heart EXCOR pediatric VAD multicenter trial results were published in 2012.[67] Although data from the trial suggest that 90% of children can be bridged to transplantation with the EXCOR, with a stroke risk of 29%, the primary cohort captured only one-fourth of all US children implanted with the EXCOR during the 3-year study period and did not include patients in whom the device was implanted as compassionate use. In a later publication, Almond and coworkers examined EXCOR outcomes in all 204 children implanted during the study period.[106] Overall survival in this unselected cohort was lower at 75%, and the risk of neurologic dysfunction was similar at 29%. Children were more likely to die on EXCOR support if they had significant renal or hepatic impairment at implantation or right ventricular failure requiring biventricular assist device support. In addition, children weighing <5 kg did significantly worse. These findings demonstrate that EXCOR survival varies considerably and depends heavily on patient characteristics at implantation, underscoring the need for careful patient selection. Specifically, excessive delay in implanting a device until renal, hepatic, or right ventricular function has significantly deteriorated increases the risk of death on EXCOR support, whereas implanting too early may also escalate mortality by unnecessarily exposing children to the risks of support (eg, stroke, death). Most of the neurologic events are secondary to left atrial cannulation; hence many centers favor ventricular apical cannulation. It is encouraging to note that even within the short 3-year time frame of this study, pediatric centers that have refined their patient characteristics over time are observing significantly lower patient mortality.[137,138]

Between 2003 and 2014, 15,745 patients who received a US FDA-approved MCS device were entered into the National Heart, Lung and Blood Institute Interagency Registry for Mechanically Assisted Circulatory Support (NHLBI INTERMACS) database. Of the 12,030 patients who received a continuous flow device, >90%

received an LVAD. PediMACS, the pediatric component of INTERMACS, began collecting all pediatric data (patients <19 years of age) in September 2012. By April 2015, 36 centers had enrolled 251 devices in 216 patients (Fig. 30.8). The durable and temporary mechanical circulatory devices that have been entered into the registry are included in Table 30.6. Among patients up to 5 years of age, pulsatile LVADs (Berlin Heart EXCOR; Berlin Heart Steglitz, Berlin, Germany) accounted for nearly 50% of implants. Among patients between 6 and 10 years of age, continuous flow LVADs began to predominate, with an overall actuarial survival at 6 months of 90% and 66% of patients undergoing cardiac transplantation by 12 months.[139,139a] In 2016 the Pediatric Interagency Registry for Mechanical Circulatory Support (PediMACS) reported the outcome of children implanted with VADs in the United States. Between September 2012 and June 2015, 200 patients underwent 222 durable VAD implants. Ninety-one patients were supported with a pulsatile-flow device and 109 (55%) with a continuous flow (CF) device. There were 28 deaths. Reported serious adverse events included infection (n = 78), bleeding (n = 68), device malfunction (n = 79), and neurologic dysfunction (n = 52).

Diagnoses leading to pediatric heart transplantation are age specific and have also changed over time. Congenital heart disease remains the most common cause of heart failure leading to heart transplantation in infants but has significantly decreased over time, whereas cardiomyopathy is increasing. Unfortunately, infants have the highest waiting period due to lack of available organs and have the highest wait-list mortality.[138,140] Analysis of the Pediatric Heart Transplant Study (PHTS) registry demonstrated an overall survival of 83% at 5 years after transplantation in the most recent era.[141] Renal failure, ECLS at the time of listing, and ECLS at the time of transplantation were correlated with worse outcomes. A review of the United Network for Organ Sharing (UNOS) database[69] demonstrated improved survival when patients are supported with VADs. The use of ECLS as a primary means of mechanical support and a bridge to cardiac transplantation in the current era is minimal, approximately 4% of all patients listed for transplant. Unlike ECMO, duration of support is not a risk factor for worse outcomes in patients bridged to transplant with VADs.

Current Perspective and Future Directions

As a general rule, VA ECLS should be considered in the acute setting, after cardiac surgery, for impaired cardiac function or when respiratory function is compromised. If recovery is not promptly achieved, conversion to VAD support is strongly recommended. There is evidence of higher posttransplant mortality in patients supported with VA ECLS compared to those with VAD support irrespective of the diagnosis.

INTERMACS reported a changing pattern in MCS intent with an increasing number of patients now receiving implant under destination therapy indications. There are multiple reasons for this trend, including a limited donor pool, improved patient selection for LVAD therapy, and increase in the number of VAD implant centers. The growing population of patients supported by durable MCS devices has had an important effect on the infrastructure required to manage patients outside of the implanting hospital and on costs to the health care system.

With more effective devices available for pediatric patients, particularly the Berlin Heart EXCOR, the percentage of patients undergoing cardiac transplantation while supported on VADs has increased from under 5% before 2002 to greater than 20% since 2009. The superiority of VAD support compared with traditional ECLS among patients awaiting transplantation is evident from a study by the Pediatric Heart Transplant Study Group.[142] Despite the tremendous improvement in pediatric MCS since the Berlin Heart EXCOR became available in the United States in 2000 and received FDA approval in 2012, patients remain at risk for significant morbidity.

Neurologic complications are high and continue to be the leading cause of mortality. Thromboembolic strokes are twice as frequent as intracranial hemorrhagic events.[143]

Options for circulatory support of pediatric patients under the age of 5 years are still limited to short-term extracorporeal devices. The need for devices suitable for small patients has been addressed by the National Heart, Lung, and Blood Institute (NHLBI), which has funded research for the development of mechanical support devices in children from 2 to 25 kg with congenital or acquired cardiovascular disease. The Pumps for Kids, Infants, and Neonates (PumpKIN) Trial launched by the NHLBI funded five novel pediatric circulatory support devices. Two investigational devices remain funded: the Jarvik (Jarvik Heart Inc., New York, New York) VAD, which is being randomized versus the Berlin Heart, and the Levitronix PediPL (Levitronix LLC, Waltham, Massachusetts) versus conventional ECMO.

Although advances in medical management, surgical techniques, and MCS for pediatric patients with cardiomyopathy or congenital heart defects continue to improve outcomes, morbidity and mortality related to pediatric heart failure continue to exist. Overall quality of life can be adversely affected in some patients due to therapy-related complications. In addition, caregivers of these patients may experience significant burden due to posttraumatic stress disorder, anxiety, depression, or poor physical health. Even though the randomized controlled trial remains the most powerful tool for unambiguous comparison of various therapies, it is a well-recognized problem that such trials to compare either pharmacologic agents or MCS devices used to treat pediatric heart failure are lacking. Obstacles exist that limit the ability to perform research on pediatric patients with congestive heart failure. For example, invasive procedures are more difficult, noninvasive procedures in small children often require anesthesia to ensure adequate data collection, and consent to participate in research must be obtained by proxy, requiring a greater level of preexisting evidence that the therapy being studied is safe and efficacious.

Intraaortic Balloon Pump

Since its invention and introduction into clinical practice in the 1960s, intraaortic balloon pumps (IABPs) have become a therapeutic tool for the management of refractory low cardiac output states in adults. In 1980, Pollock first described the use of an intraaortic balloon pump in pediatric patients with the advent of modified equipment and pediatric-sized balloon catheters. The IABP is a polyethylene balloon mounted on a catheter, which is usually inserted into the aorta via the femoral artery. The balloon is guided into the descending thoracic aorta approximately 2 cm from the subclavian artery. The balloon pump works by inflating during diastole (after aortic valve closure) for improved retrograde coronary flow augmentation; the balloon then deflates before systole to decrease left ventricular afterload. Cardiac output may be augmented by as much as 40%, decreasing left ventricular stroke work and myocardial oxygen requirements. The pump is available in a wide range of sizes (2.5-50 mL) and is driven by an external console. The use of an intraaortic balloon pump to support 24 postoperative cardiac patients with ages between 7 days and 17.5 years with low cardiac output syndrome despite optimal repair and maximal medical support resulted in successful separation from IABP in 18 out of 24 patients (75%) and 15 (62%) long-term survivors.[144] Major complications associated with increased mortality included two patients with limb ischemia and one patient

with both limb and mesenteric ischemia, which resulted in a fatal outcome.[144] Additional complications included bleeding that necessitated reexploration of the chest and sepsis. A similar review of 29 patients supported with IABP for medical, postoperative surgical, and bridge-to-transplant indications demonstrated survival to hospital discharge of 18 of 29 patients (62%). Advantages of IABP include its relative ease of use and its placement without surgical dissection. Disadvantages include infrequency of use, limitations of an isolated left ventricular support modality, contraindication with certain anatomy/physiology (eg, patent ductus arteriosus or aortic insufficiency), and serious complications that include mesenteric ischemia and arterial injury. In children, failure to augment cardiac output can occur due to a highly elastic aorta. Pediatric IABP catheters differ from adult catheters in a variety of ways. The catheter shafts are smaller (4 or 5 French) with balloon sizes of 0.75 to 10 mL. Early failed reports of the use of IABP in children were primarily due to the use of inappropriately sized balloons and failure to gate to the ECG at fast heart rates. Adequate timing of the balloon inflation and deflation is essential; radial artery tracings were used in the past to aid timing of balloon inflation, but rapid heart rates led to significant timing errors. The use of M-mode echocardiography to aid in timing of the balloon inflation and deflation with aortic valve opening and closing has significantly improved the efficiency of intraaortic balloon pumping therapy. As a result of these difficulties, the use of intraaortic balloon pumping therapy in the pediatric population has remained limited to a small number of patients in a few institutions.[145]

Conclusions

Principles of MCS require an individualized approach. Indications include a variety of disease processes leading to LCOS such as myocarditis, septic shock, and surgery to repair congenital heart defects. Short-term experience with mechanical devices had been limited to ECLS, but pediatric experience with VADs is growing. Early institution of ECLS and transition to a VAD are necessary to avoid irreversible organ failure.

Pediatric MCS has demonstrated a number of significant advances; however, the limited options for mechanical support of the failing circulation in small children continue to be a challenge. Despite positive outcomes, several significant side effects remain, including bleeding, stroke, and infection. Patient selection, timing of support, device selection, and perioperative care continue to be critical components in a successful outcome for these patients.

CHAPTER 31

Echocardiographic Imaging

Noninvasive Cardiac Diagnostics

John L. Bass, Charles W. Shepard

PEARLS

- Echocardiography is a multipurpose imaging modality that is readily available and useful in a variety of intensive care settings.
- Echocardiography is employed in both noninvasive (transthoracic) and invasive methods (transesophageal and intracardiac).
- Echocardiography is the modality of choice in the evaluation of structural defects of the heart, ventricular function, volume status, valve function, degree of pulmonary hypertension, pericardial effusion, vascular abnormalities, cardiovascular communications, and cardiac function during extracorporeal membrane oxygenation/ventricular assist device placement or weaning.
- Echocardiography may be used for intraoperative or postoperative assessment, to guide intracardiac procedures, or for vascular access.
- Echocardiographic evaluations of cardiovascular communications provide valuable physiologic information about the connecting chambers/structures.

Introduction

Echocardiography is a relatively noninvasive technique that facilitates examination of the anatomy and flow in the heart and great vessels. The technique was first reported in the mid-1970s, initially as M-mode images with a single crystal transducer that demonstrated distance of structures from the chest wall and motion over time. This was rapidly expanded to two-dimensional (2D) imaging by moving the transducer mechanically through a sector, or forming a transducer with multiple crystals and electronically steering the echo beam. In the 1980s the signal and processing were further modified to detect the direction and velocity of blood using

Doppler. Multigated pulsed Doppler was used to map flow throughout a sector and paint over the 2D image to provide an image of flow combined with anatomy. This combination of anatomy and flow has made echocardiography the primary diagnostic tool for congenital heart disease, supplanting cardiac catheterization. Further miniaturization allowed transducers to be placed at the end of endoscopes (transesophageal echocardiography [TEE]) and on small transducers for intravaginal imaging of the fetus, even on the end of catheters for intracardiac echocardiography (ICE). Increasing computer processing power and speed provides the ability to generate real-time three-dimensional images. Echocardiography is limited by the ability to obtain images ("acoustic windows"), and patient cooperation is often necessary. Conditions that interfere with the ability of ultrasound to reach the cardiovascular structures from the chest wall, such as pneumothorax, pulmonary disease, or surgical resection of the thymus at cardiovascular operations, may also limit the ability to get good information. In these instances, TEE, a technique that images the heart from behind, may bypass these impediments and provide a different set of "windows" from which the heart can be imaged. The majority of patients, however, have adequate windows for ultrasound penetration so that echocardiography provides a primary diagnostic tool for evaluation of patients in the pediatric intensive care unit. Unlike Schroedinger's cat, the act of observation does not alter the state of the patient. The patient usually does not require additional sedation, does not have to be transported to a catheterization laboratory or radiology suite, and no contrast medium is necessary. Because of portability and the rapidity with which information can be acquired, echocardiography is ideally suited to serial observations and assessing the effects of therapy.

Diagnosis of Structural Defects

The full spectrum of congenital heart disease can be diagnosed using echocardiography. The connections, morphology of the atria and ventricles, anatomy, and defects of the semilunar and atrioventricular valves are easily defined. The relationships of vessels, valves, and defects of the atrial and ventricular septum are outlined in tomographic analysis. One disadvantage of echocardiography is that it is a tomographic technique, and the images of structures can be obtained from multiple windows with differing appearances. This led to a new generation of surgeons and interventional cardiologists who are able to recognize the different structures from these slices of anatomy and even perform interventional catheterization procedures while watching the ultrasound image alone without fluoroscopy. A full description of the diagnosis of congenital heart disease is beyond a single chapter on the uses of echocardiography in the ICU. Instead, we focus on how echocardiography helps in the evaluation of clinical problems that arise in patients admitted to the ICU for illness or those recovering from cardiovascular surgical or interventional procedures. Specifically, we discuss using echocardiography to assess ventricular function, volume status, valve function, pulmonary hypertension, pericardial effusion, vascular problems, catheter manipulation, transcatheter cardiac devices, ventricular assist device, and physiology derived from cardiovascular communications.

Ventricular Function

Diminished ventricular systolic function can account for hypotension or low cardiac output. This is measured traditionally for the left ventricle by looking at the percentage of decrease in an M-mode–derived internal diameter (diastolic left ventricular [LV] dimension-systolic LV dimension/diastolic LV dimension) or shortening fraction (Fig. 31.1). Normally this ratio is above 28%, and lower values indicate decreased LV systolic function. A more familiar calculation of systolic function is the LV ejection fraction. This calculation is the percentage of volume ejected by the left ventricle in systole using 2D measurements (diastolic volume-systolic volume/diastolic volume) and normally is 55% or above (Fig. 31.2). Mild dysfunction is in the range of 45% to 50%, and ejection fractions below 45% indicate significant systolic dysfunction. Calculations of ejection fraction usually are derived from an assumption of LV geometry (spinning the left ventricle around its long axis yields a true representation of its actual volume). When the left ventricle enlarges, it may assume a more spherical shape and these formulas become less accurate. Abnormalities of the ventricular septum motion can interfere with this calculation, as seen with ischemia, conduction abnormalities, and pressure or volume load of the right ventricle. Damage to the myocardium in select areas may produce regional wall motion abnormalities, particularly with abnormal perfusion or selective damage with global disease. Ejection fractions calculated in this circumstance are also less accurate. Accuracy also depends on good definition of the endocardium so that the LV chamber can be traced. In larger patients, injecting protein or lipid microspheres that are small enough to cross the pulmonary capillary bed and opacify the left ventricle can yield a clearer delineation of the LV endocardial border. However, these agents are not approved for use in children and contraindicated in the presence of intracardiac right-to-left shunts. Calculation of right ventricular systolic function is more difficult as the right ventricle has a more complex shape with different inflow and outflow geometries. This can be approximated from a four-chamber view and an inflow/outflow view from subcostal windows. But the most accurate method is careful reconstruction of the right ventricle from multiple slices or three-dimensional imaging.

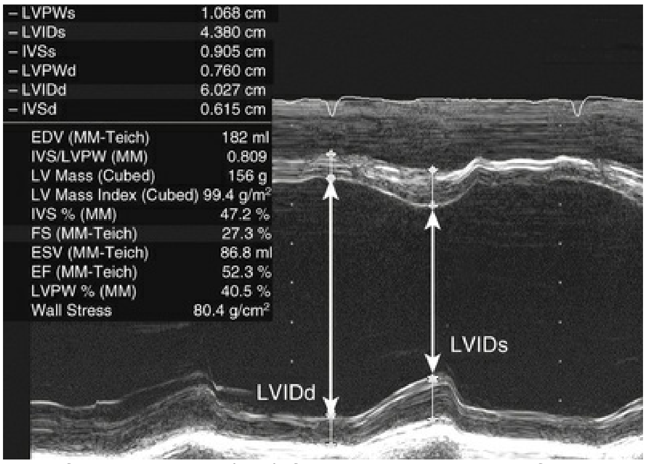

FIG. 31.1 Left ventricular (LV) function measured from an M-mode echocardiogram. The ultrasound beam passes through the left ventricle,

and the motion relative to the chest wall and changes in thickness and diameter are represented on the vertical axis. Time is on the horizontal axis. Shortening fraction *(FS),* a measure of LV systolic function, is calculated as the difference in LV diastolic *(LVIDd)* and systolic *(LVIDs)* dimensions, divided by the diastolic dimension.

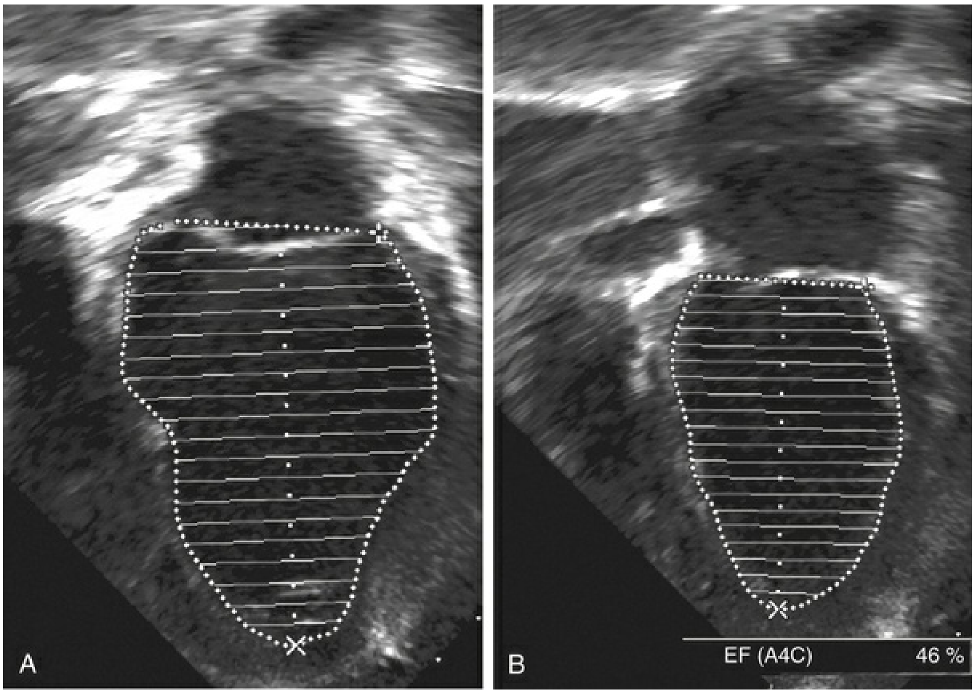

FIG. 31.2 Left ventricular ejection fraction. The ejection fraction (EF) is calculated from the difference in the diastolic volume (A), and the systolic volume (B) is divided by the diastolic volume. Normally the ejection fraction is 55% or above, with low normal 48% to 54%, mildly depressed 40% to 48%, moderately depressed 35% to 40%, and severely depressed less than 35%.

Assessing Volume Status

The diastolic size of the ventricles is dependent on the preload and compliance. In a patient with normal myocardium, dehydration can produce small diastolic dimensions that increase with rehydration. This principle is useful in patients who have undergone acute large fluid shifts as seen after cardiopulmonary bypass. A small RV or LV size in the presence of hypotension, particularly with low central venous pressures, is an indicator of insufficient preload to fill the ventricular chamber. When compliance is decreased, the ventricular chambers may be small despite what would normally be considered adequate filling pressure. Postoperative tetralogy of Fallot patients have decreased right ventricular compliance due to RV hypertrophy and require a higher CVP to expand the RV and generate adequate cardiac output.

A corollary is conservation of mass when a larger ventricular cavity suddenly has a lower diastolic volume. This can occur with acute control of hypertension in an

infant. Decrease in markedly elevated afterload with LV failure causes a sudden decrease in the diastolic volume. As the ventricular muscle is less stretched with a smaller chamber size, the ventricular walls become thicker (conservation of mass). This can also occur after cardiac transplantation. The large cavity left by the recipient heart allows implant of a larger donor organ. The new ventricle accommodates to the lower diastolic filling in a smaller person by decreasing diastolic volume. Again, LV mass is conserved by increasing the wall thickness. Over time, the "inappropriate" hypertrophy regresses.

Measuring Valve Function

Although 2D imaging of valves provides the anatomy of abnormalities, valve function is better assessed using Doppler. A combination of spectral and color flow Doppler yields measurements of timing and pressure differences, while color flow Doppler shows the relationship of abnormal flow to anatomic structures. For ease of discussion, we divide this into stenosis and regurgitation of semilunar and atrioventricular valves.

Semilunar valves are discrete in location, and the simplification of the Bernoulli equation (pressure difference = 4 × [peak velocity]^2) works well to calculate a systolic gradient. For the pulmonary valve, the peak instantaneous pressure gradient correlates best with the peak-to-peak gradient measured in the cardiac catheterization laboratory. For the aortic valve, however, the mean Doppler derived systolic pressure gradient seems to correlate best with the peak-to-peak gradient measured in the cardiac catheterization laboratory. Regurgitation is assessed directly by observing the size and distribution of the regurgitant jet on color flow Doppler and by evaluating chamber sizes affected by the regurgitant flow.[1] The length of the regurgitant jet is affected by the velocity difference across the valve. Pulmonary insufficiency usually reflects a lower diastolic pressure than aortic insufficiency, and significant regurgitation may produce a shorter regurgitant jet than an equivalent degree of aortic insufficiency. The regurgitant flow comes from connected vascular systems for both pulmonary and aortic valves. Significant pulmonary or aortic insufficiency produces retrograde diastolic flow from the main pulmonary artery or abdominal aorta, supplementing assessment of the size of the regurgitant jet.

Atrioventricular valve stenosis and regurgitation can also be measured by spectral and color flow Doppler. The peak instantaneous gradient of tricuspid or mitral stenosis is less meaningful than the mean gradient derived from spectral Doppler. Obstruction may be reflected by enlargement of the connected atrial chamber in both instances. Atrioventricular valve regurgitation is more difficult to quantify. The jet length is greater with higher velocities independent of the amount of leakage. The regurgitant jet may move during systole or entrain along an atrial wall.[2,3] The proximal isovelocity surface area (PISA) has been used in adult patients to overcome this, measuring the area of a hemispheric shell of increasing velocity and velocity at which aliasing occurs.[1] This has less accuracy in pediatric patients because of multiple jets of regurgitation and the location of the regurgitant orifice. Systolic reversal of flow in the vessels connected to the chamber receiving the regurgitant flow (inferior vena cava or pulmonary veins) occurs when significant regurgitation is present.

Postoperative/procedural evaluation of valve competency or stenosis often is

needed in the ICU, particularly because TEE in the operating room performed immediately postoperatively may not be accurate. The valve can be assessed for residual obstruction or regurgitation after balloon dilation of critical stenosis of the pulmonary or aortic valve. Difficulty weaning from ventilator support after atrioventricular septal defect repair may result from significant mitral valve regurgitation from dehiscence of the repair.

Evaluating Pulmonary Hypertension

Physiologic insufficiency of the tricuspid and pulmonary valves is common even in normal individuals and can be used to assess right ventricular and pulmonary arterial pressures. The peak velocity of tricuspid insufficiency reflects the peak systolic pressure difference between the right ventricle and right atrium. This normally ranges between 1.8 and 2.9 M/s. In this range of velocities, with normal right atrial pressure, pulmonary artery systolic pressure is normal. Higher velocities indicate elevated pulmonary artery systolic pressure[4] that may result from elevated pulmonary vascular resistance, right ventricular outflow obstruction, or transmission of systemic pressure from a ventricular septal defect (VSD) or patent ductus arteriosus (PDA). The end-diastolic velocity of pulmonary insufficiency can be used to calculate pulmonary artery diastolic pressure, as this reflects the difference in end-diastolic pressure between the pulmonary artery and right ventricle. This normally ranges between 0.5 and 1.5 M/s. With higher velocities, assuming a normal right ventricular diastolic pressure, pulmonary artery diastolic pressure can be estimated (Fig. 31.3). These calculations are especially useful with elevated pulmonary vascular resistance or indirect elevation in pulmonary artery pressure with elevated left atrial or pulmonary venous pressures.

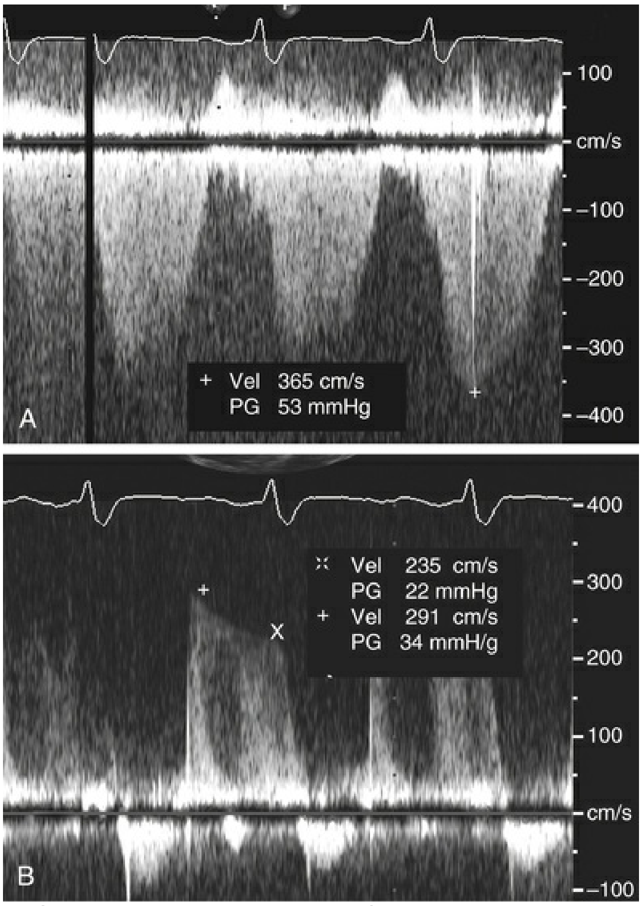

FIG. 31.3 Spectral Doppler tracings from pulmonary and tricuspid regurgitation in a patient with pulmonary hypertension. High-velocity tricuspid regurgitation (A) yields a calculated right ventricular systolic pressure 53 mm Hg above right atrial pressure (often assumed to equal central venous pressure). The pulmonary insufficiency signal (B) confirms that pulmonary artery pressure is elevated (end-diastolic velocity yields a calculated pulmonary artery diastolic pressure 22 mm Hg above right ventricular diastolic pressure). The velocity at the start of diastole may be an indicator of the mean pulmonary artery pressure.

The regurgitant velocities measured by Doppler across the pulmonary and tricuspid valves increase with increasing pulmonary artery pressure. At very high velocities, these estimates may be less accurate (any error in velocity is squared). Hypertrophy of the right ventricle and the systolic contour of the ventricular septum (flattened or displaced toward the left ventricle) have also been used to evaluate systemic or higher right ventricular systolic pressure. In addition to the velocities of right-sided regurgitant flow, the velocity and direction of intracardiac shunts are useful in this assessment (in the absence of restriction or obstruction). Effectiveness of therapy directed to lower pulmonary artery resistance can be monitored noninvasively with a combination of these methods.

Assessing Pericardial Effusion

Pericardial effusion can occur in a number of circumstances: from primary pericardial infections (eg, bacterial [including tuberculosis], viral), a “sympathetic”

collection in pulmonary infection, diffuse inflammatory processes (eg, uremia, post–bone marrow transplant, postpericardiotomy syndrome), or with mechanical trauma (eg, erosion of an atrial septal defect device, perforation by an umbilical venous catheter). The presence of an abnormal amount of pericardial fluid is easily recognized by echocardiography with a separation between the visceral and parietal pericardium that has decreased acoustic density. This must be distinguished from fluid in the pleural space, or ascites. The heart is connected to pulmonary and systemic veins, as well as the great arteries, and pericardial effusions usually do not extend behind the left atrium or in front of the great arteries. Pleural effusions can occupy these areas and may extend around the lower lobes of the lungs. This fluid may accompany atelectasis that can be penetrated by the ultrasound beam (Fig. 31.4).

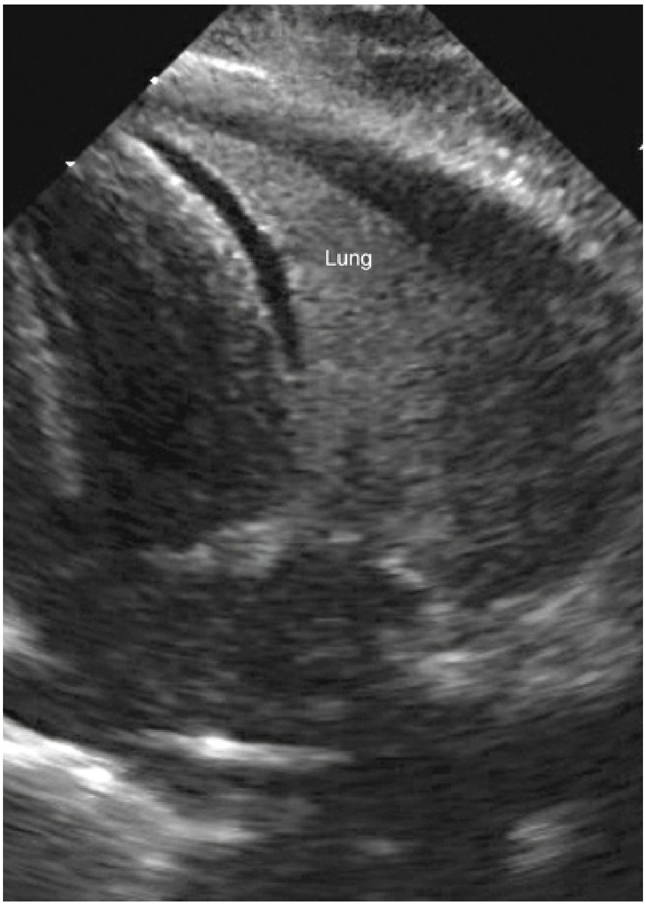

FIG. 31.4 Two-dimensional echocardiogram performed from a left subcostal window. The apical left lung *(Lung)* is atelectatic, allowing reflection of ultrasound typical of tissue. There is small associated pleural effusion.

Excess pericardial fluid may interfere with filling of the heart by compromising expansion of the ventricular chambers. The amount of fluid that compromises filling depends on the speed with which the fluid accumulates. Fluid that accumulates rapidly (over minutes or hours) does not allow the pericardium to stretch so that a small volume may limit ventricular filling. Fluid accumulation over days or weeks allows the pericardium to stretch, and larger volumes of fluid may accumulate

without causing compromise. The absolute amount of pericardial fluid may not indicate the degree of embarrassment.

Clinically, patients with compromised filling of the ventricles have tachycardia, tachypnea, and hypotension. True tamponade also has a pulsus paradoxus, an exaggerated respiratory variation of the systemic systolic blood pressure. This observation requires obtaining the blood pressure with a stethoscope as it is not recognizable with oscillometric blood pressure recorders. This is accompanied by late diastolic inversion of the right atrium[5] and/or early diastolic collapse of the right ventricle[6] (Fig. 31.5) and an inspiratory decrease of the velocity of blood ejected from the left ventricle.[7] The change in velocity must be considered carefully as the heart can "swing" in large effusions, changing the angle of incidence between flow and the echo beam. These signs indicate the need for emergent decompression of the pericardial space. Even in the absence of signs diagnostic of tamponade, a decrease in heart rate with improvement of blood pressure may be observed with removal of pericardial fluid, suggesting a lesser but real degree of compromise.

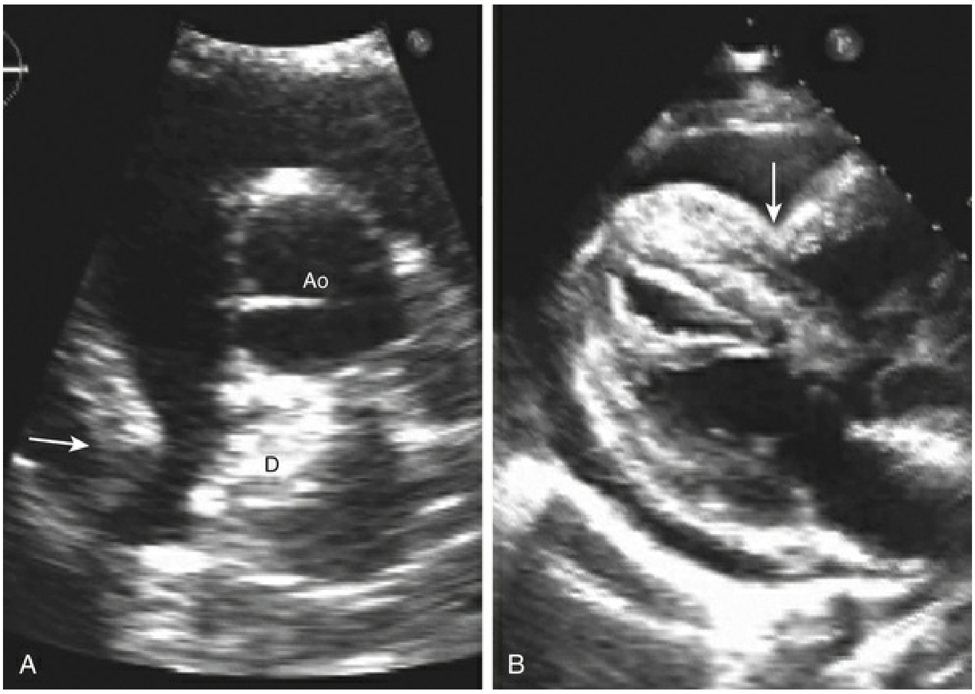

FIG. 31.5 Pericardial effusion in a patient with erosion of an Amplatzer Septal Occluder device *(D)* in contact with the aorta *(Ao).* Tamponade is indicated by diastolic collapse of the right atrium (*arrow*, Panel A) and right ventricle (*arrow*, Panel B). Erosion of the device is suggested by syncope, chest pain, or increasing exercise intolerance after implantation.

Removing fluid from the pericardium is easily and safely accomplished under echocardiographic guidance. The location of a safe entrance to the pericardium can be determined by finding a window where the pericardial space is a short distance from the skin, and there is no intervening lung. Traditionally this has been from a subxiphoid position. However, reaching the pericardial space through this approach could be challenging due to interposition of the liver, and the largest accumulation of fluid may not be reached through this approach. An easier approach may be from

apical, parasternal, or even anterior/superior locations. Depending on adiposity, the fluid may be only a centimeter away from the skin. Lung that expands to cover the pericardial window with inspiration increases the risk of perforation of lung tissue and pneumothorax during the procedure.

Once a safe and close location to access a large accumulation of pericardial fluid has been selected, the passage of the pericardiocentesis needle into the pericardial space can be observed by echocardiography. This significantly reduces the chance of perforating the heart or coronary arteries. Visualizing that the needle is within the pericardial space is reassuring when the effusion is bloody. Once pericardial fluid is obtained, a guidewire is introduced into the posterior pericardium, followed by a dilator and placement of a pericardiocentesis catheter. As the fluid is evacuated, the decrease in effusion size can also be observed by echocardiography (Fig. 31.6). This procedure can be safely performed at the bedside without moving the patient to the cardiac catheterization laboratory or bringing C-arm fluoroscopy to the patient. Whether or not to leave the pericardiocentesis catheter in place at the end of drainage is a clinical decision. The procedure is sterile, and contamination of the pericardial space is unlikely.

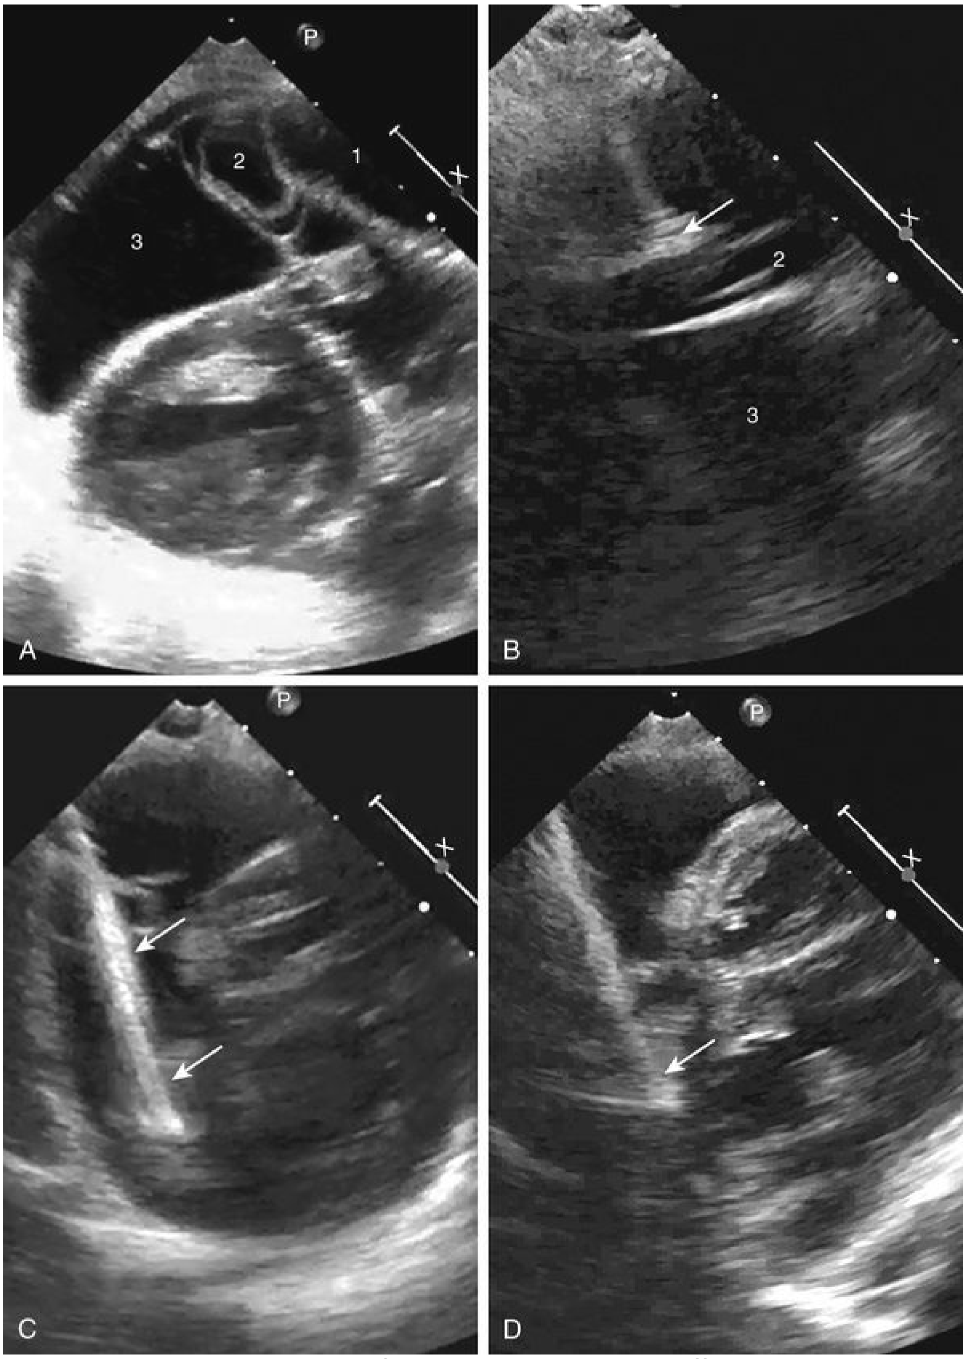

FIG. 31.6 Drainage of a complex pericardial effusion under echocardiographic guidance. In A, three separate chambers of a loculated effusion are present. In B, a needle is sequentially advanced through each chamber (*arrow* at limit of chamber 1). In C a guidewire *(arrows)* has been advanced to chamber 3. In D, chambers 2 and 3 have been evacuated by withdrawing a pigtail catheter *(arrow)* sequentially. The effusion was completely drained.

Vascular

Echocardiography provides a clear picture of catheters in veins and arteries. In addition to location, the presence of thrombus associated with the catheter can be

identified. In some instances, echocardiography can be used to position catheters and manipulate them through channels or intracardiac connections.[8] Indications to evaluate a catheter include persistent pleural effusions or facial edema in a postoperative patient, evaluation for access in a patient with previous indwelling catheters, arrhythmias in a patient with a central venous line that could fall through the tricuspid valve into the right ventricle, any infant with an umbilical venous line who is getting an echocardiogram for another reason, or direction of a balloon atrial septostomy catheter in a newborn infant with dextro-transposition of the great arteries.

Thrombi associated with venous catheters can vary from a fibrin cast left behind when the catheter is removed, to thrombi within the vessel where a catheter resides, to a thrombus located where the tip of the catheter comes in contact with cardiac structures (Fig. 31.7). When the left innominate vein is occluded with thrombus, this may affect drainage from the thoracic duct. Early work suggests this may lead to chylous pleural effusions, or in the setting of Glenn/Fontan patients, protein-losing enteropathy or plastic bronchitis. Thrombi seem to be less common with umbilical venous catheters but can form across the foramen ovale when the catheter extends from the ductus venosus into the left atrium despite an apparently good position on a chest roentgenogram (Fig. 31.8). This raises the possibility of air being instilled into the systemic circulation. Even when the catheter does not extend into the left atrium, the tip of the catheter is aimed at the foramen ovale, and injected fluid streams toward the left atrium. Also of concern is the possibility of erosion of the catheter through the atrial wall. This may be more likely when the catheter extends across the atrial septum (Fig. 31.9).

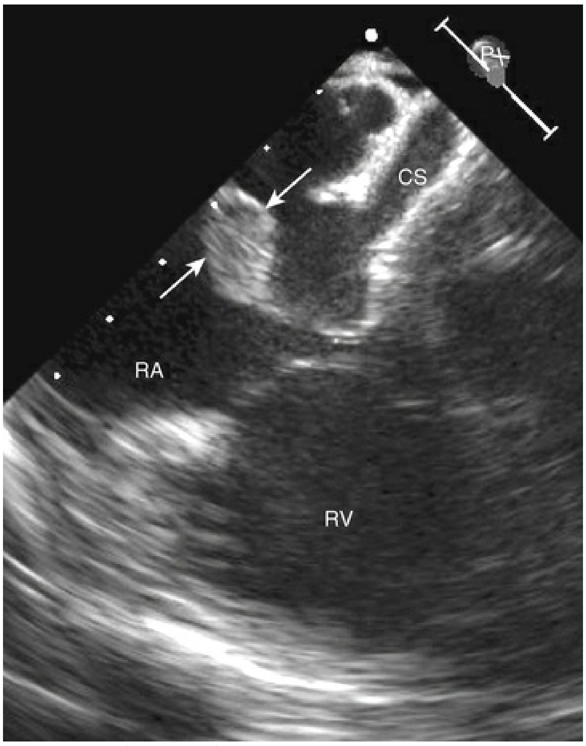

FIG. 31.7 A thrombus *(arrows)* is present attached to the right atrial *(RA)* wall. The thrombus formed at the tip of a central venous catheter. *CS*, coronary sinus; *RV*, right ventricle.

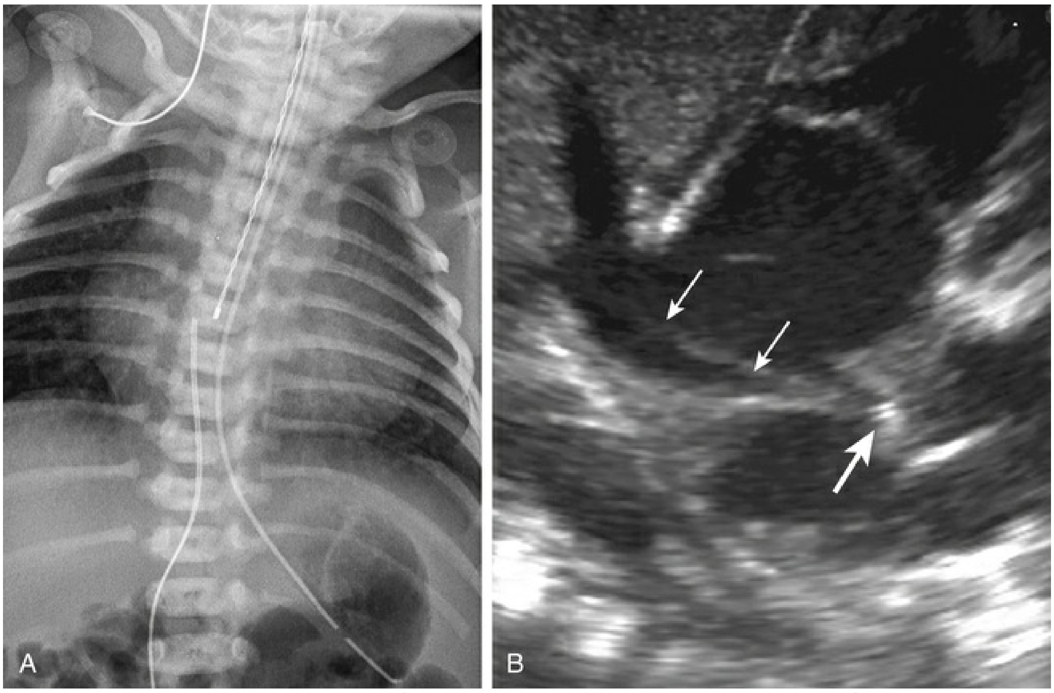

FIG. 31.8 Fibrin sheath from an umbilical venous catheter. On chest roentgenogram (A) the catheter tip appears to be in the mid right atrium. After removal of the catheter, echocardiography (B) reveals a fibrin sheath remaining *(small arrows)*, and the tip of the thrombus extends across the foramen ovale *(larger arrow)*.

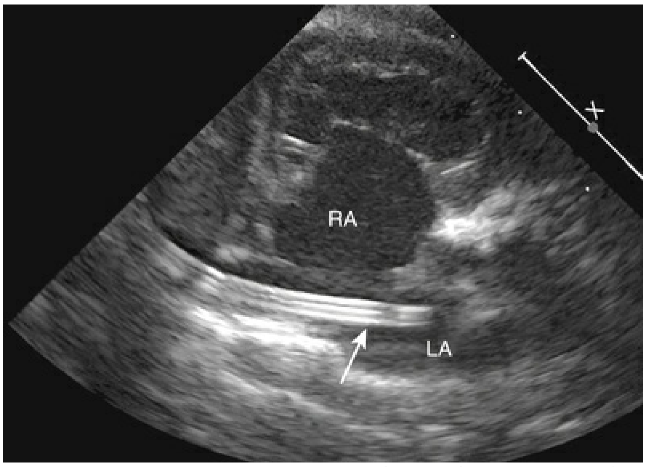

FIG. 31.9 An umbilical venous catheter *(arrow)* extending from the right atrium *(RA)* across the foramen ovale in the left atrium *(LA)*.

Vascular access has been significantly improved by direct ultrasonographic visualization of the vessel during puncture. The needle trajectory can be followed as it enters the vessel, and care can be taken to direct the entry point to “12 o'clock” position (Fig. 31.10) so that passage through the vascular lumen is ensured and the number of punctures to obtain access is reduced. This might lower the incidence of

vascular thrombosis associated with acute vascular access and should replace the classic approach of penetrating a vessel for access using landmarks and touch that becomes repeatable only with experience. The limitations of this technique are that landmarks (eg, the inguinal ligament) may be hidden by the ultrasound transducer, and care must be taken not to penetrate the sterile probe cover with the needle.

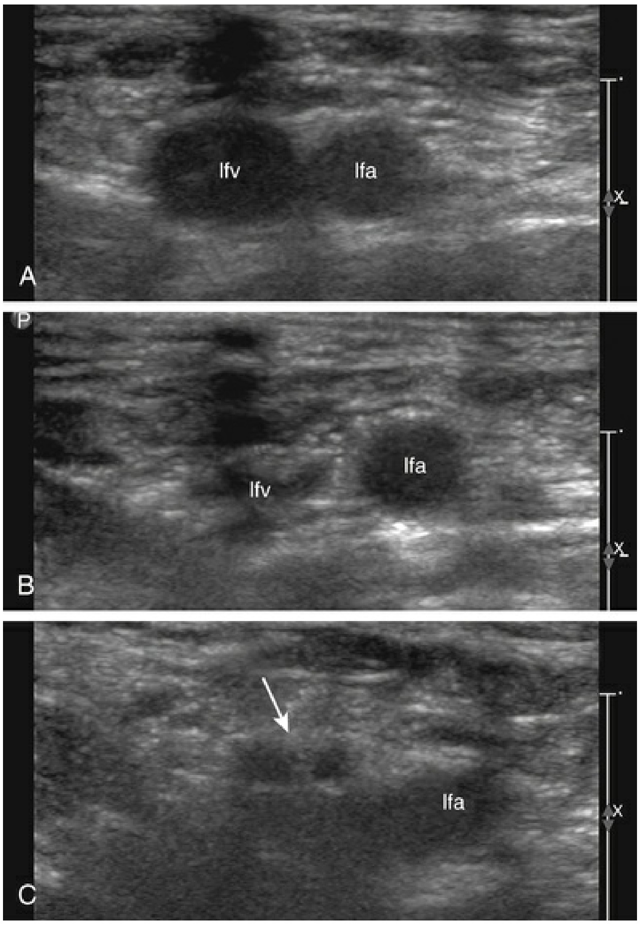

FIG. 31.10 Vascular access obtained under ultrasound guidance. In A the left femoral artery *(lfa)* and vein *(lfv)* are imaged. In B increased pressure on the transducer causes compression of the vein. The needle entering the vein can be seen at 12 o'clock *(arrow)* in C.

Caval anatomy can be important in care of children in the ICU. Although persistence of a left superior vena cava occurs with some frequency, the vessel usually connects to the coronary sinus and upper left systemic venous return reaches the right atrium. Rarely this can be associated with fenestrations of the coronary sinus that allow systemic venous blood to enter the left atrium or pulmonary venous blood to enter the coronary sinus (the equivalent of an atrial septal defect—a "coronary sinus atrial septal defect"). Another possible cause of cyanosis associated with a persistent left superior vena cava is direct attachment of the vein to the left atrium instead of the coronary sinus (Fig. 31.11). In this instance, the entirety of the left upper systemic venous return enters the left atrium directly, a cause of persistent cyanosis from birth that is not caused by pulmonary disease. This is easily resolved by transcatheter occlusion of the connection. After some surgical repairs (eg, cardiac

transplantation) the anastomosis of the superior vena cava may be compromised and stenotic yielding higher velocity flow (Fig. 31.12), particularly when there has been a previous Glenn anastomosis. This may be manifested by edema of the face or upper body. Caval stenosis can be treated by stenting the narrowed segment.

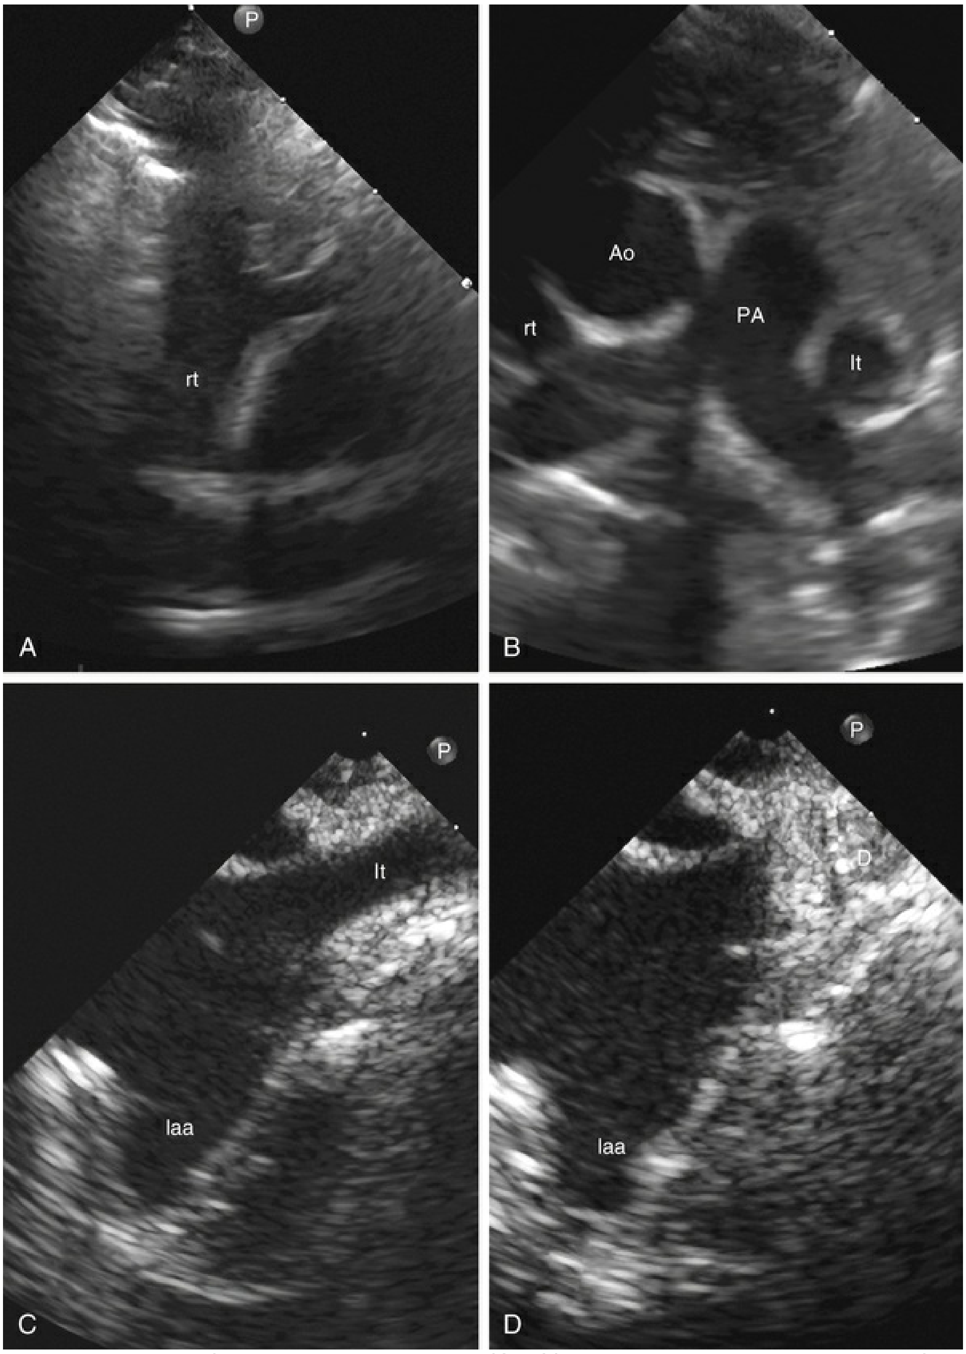

FIG. 31.11 Left superior vena cava *(SVC)* connecting directly to the left atrium. The normal right SVC *(rt)* is seen in A from a suprasternal notch view. A short axis view (B) shows the right SVC and left SVC *(lt)* in cross section to the right and left of the aorta *(Ao)* and pulmonary artery *(PA).* Transesophageal imaging (C) shows the left SVC connecting directly to the left atrium. In D, a device (D) has been placed occluding the entrance of systemic venous blood to the systemic arterial circulation. *laa,* left atrial appendage.

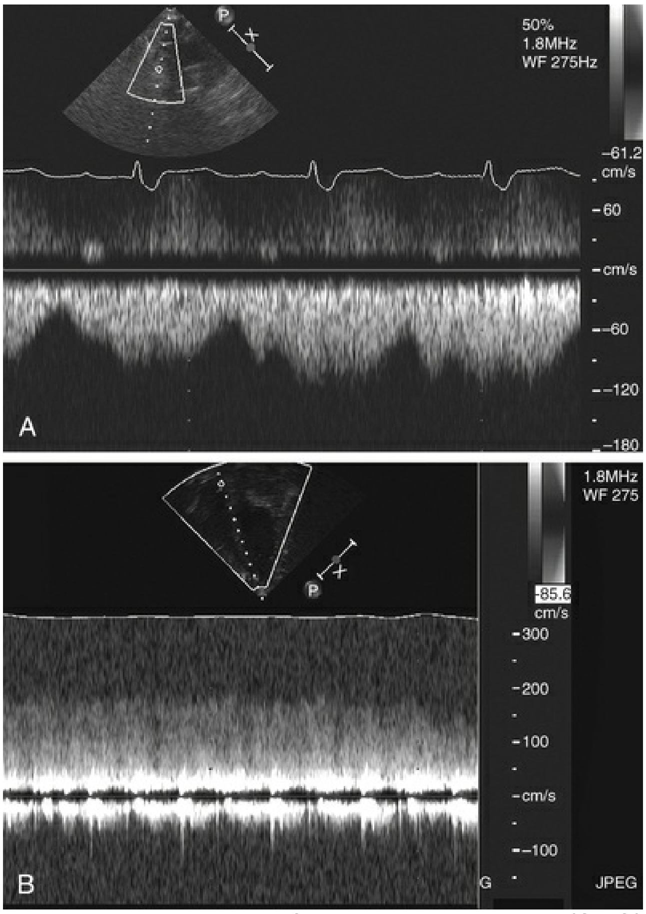

FIG. 31.12 Doppler recordings of superior vena caval *(SVC)* flow. The signal in A has a normal low-velocity signal and phasic variation with respirations and the cardiac cycle. The recording is made from the suprasternal notch, producing a negative signal. The signal in B is high velocity and continuous without variation, a result of SVC obstruction. The recording is made from a subcostal widow, producing a positive signal.

Interruption of the inferior vena cava with azygous continuation leaves the hepatic venous return directly to the floor of the right atrium. This is not a cause of cyanosis. However, the connection of the inferior vena cava can be altered by surgical repair. Redirection of inferior vena caval flow may occur with surgical repair of an atrial septal defect, but the cyanosis is obvious at the time of surgery. Orientation of a surgical patch so that inferior caval flow is directed through a residual atrial communication may be less obvious. Subtle Doppler flow patterns may be difficult to elucidate, but an echo contrast study from the lower half of the body is diagnostic. Fluid rapidly injected through a small bore needle or catheter reduces pressure where it enters the circulation, causing tiny gas bubbles to form transiently in the vessel or chamber. These persist for a short period of time before collapsing back into solution and are large enough that the pulmonary capillaries filter them out. These microbubbles reflect ultrasound providing a dense and graphic demonstration of the course of the blood in which they are produced and do not enter the systemic circulation from systemic venous injection unless there is an abnormal

communication with a right-to-left shunt[9] (Fig. 31.13). Cryptogenic stroke may be associated with a transient right-to-left shunt (paradoxical embolus) through a patent foramen ovale (PFO). This is diagnosed with an echo contrast study during a Valsalva maneuver (transiently increasing systemic venous return and right atrial pressure) in patients who can cooperate. When there is no other cause of a stroke, the PFO may be closed with a transcatheter device.

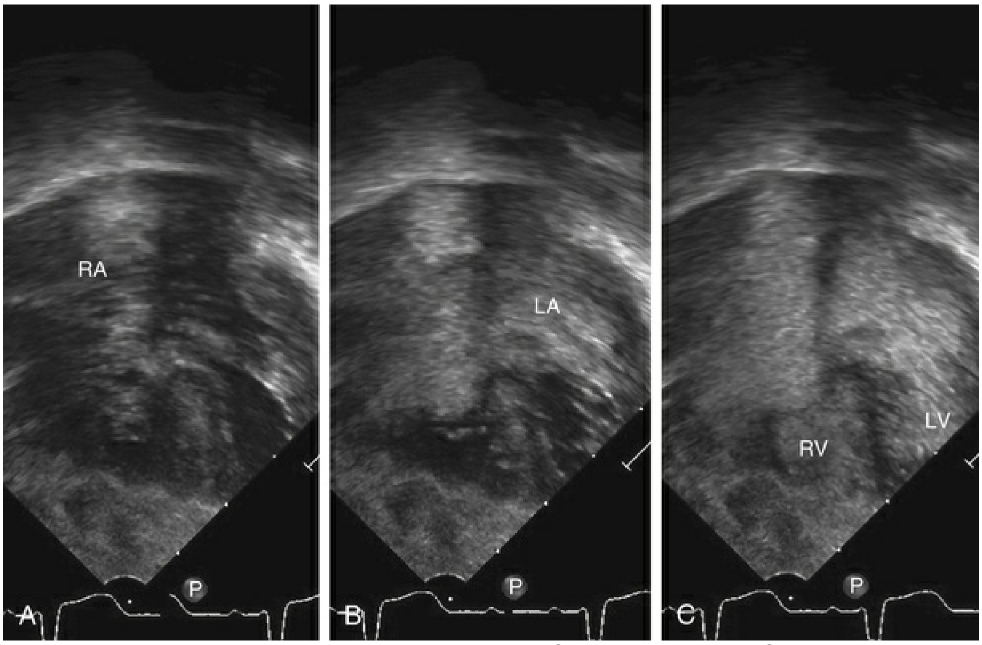

FIG. 31.13 An echo contrast study is performed injecting from the lower half of the body after repair of a complete atrioventricular septal defect. The right atrium (RA) is opacified first in A. In B the contrast effect has passed across an atrial septal communication to the left atrium (LA), and in C right *(RV)* and left *(LV)* ventricles are opacified. This documents a significant residual right-to-left shunt at atrial level.

Catheter Manipulation

The first catheter manipulation guided by echocardiography was probably balloon atrial septostomy. Patients with complete transposition of the great arteries often require improved mixing between the pulmonary and systemic circulations. In these cases, enlarging a small atrial communication can be lifesaving. Balloon atrial septostomy was traditionally performed under fluoroscopy in the cardiac catheterization laboratory. However, the entire procedure can be accomplished under ultrasound guidance at the bedside,[10] from access to crossing the atrial septal communication and pulling the inflated balloon across the atrial septum (Fig. 31.14). This avoids the need to move a fragile cyanotic newborn infant from the ICU to the cardiac catheterization laboratory. Visualization of the cardiac structures and balloon prevents inadvertent withdrawal from the LV cavity. When the umbilical vein is selected as the route of approach, but an umbilical venous catheter cannot be advanced into the inferior vena cava, direction of a catheter through the ductus venosus under echocardiographic guidance is possible (Fig. 31.15).

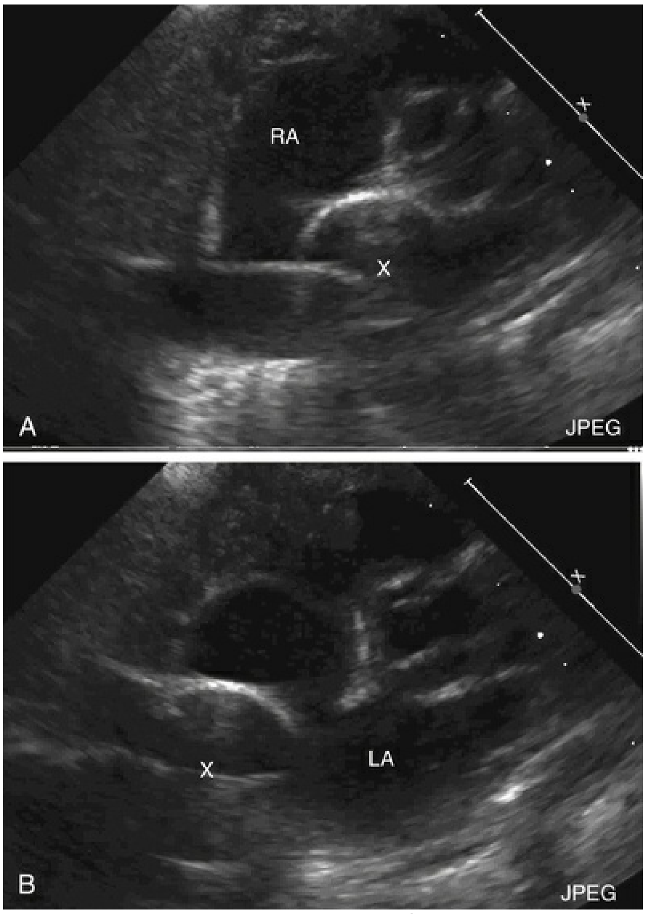

FIG. 31.14 Echocardiographic guidance of a balloon atrial septostomy. The inflated balloon *(X)* fills the left atrium (panel A). The balloon was sharply withdrawn across the atrial septum stopping at the inferior vena cava, leaving the left atrium *(LA)* empty with a hole in the atrial septum (panel B).

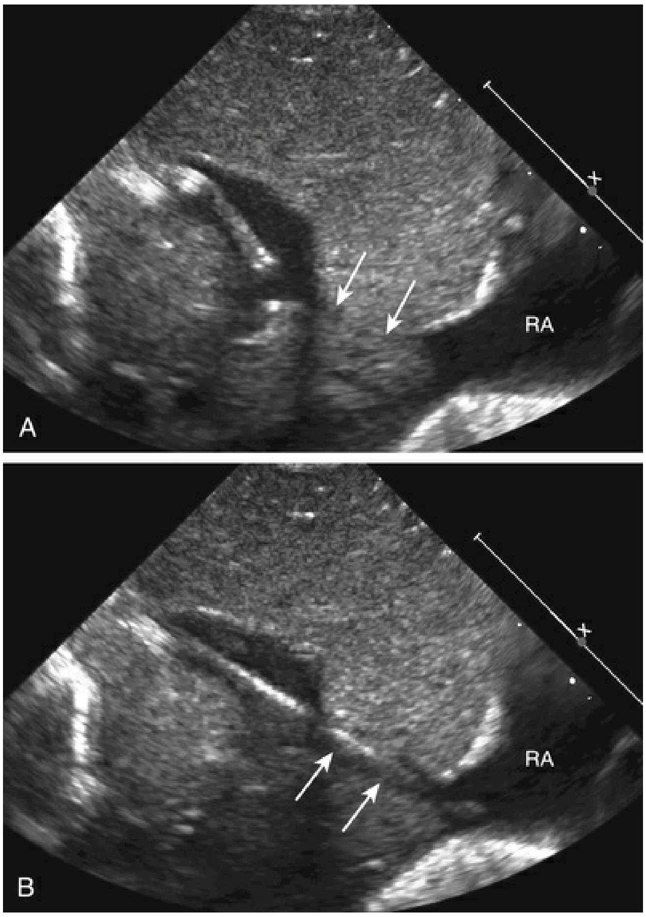

FIG. 31.15 Catheterization of the ductus venosus under echocardiographic guidance. Imaging is parallel to the long axis of the body with the head to image right and feet to image left. *Arrows* in A indicate the ductus venosus channel, while an angled glide catheter is seen proximally in the liver. In B, the catheter is rotated clockwise and advanced across the ductus venosus into the right atrium *(RA).*

Devices

Over the past 15 to 20 years transcatheter devices have been developed that allow closure of simpler congenital heart defects, such as patent ductus arteriosus, atrial, and ventricular septal communications. Placement of these devices is enhanced by cardiac ultrasound—transesophageal, intracardiac, and epicardial. Surgically placed sutures may inadvertently impinge on adjacent cardiac structures (eg, the conduction system), and transcatheter devices have the same potential. An atrial septal defect occlusion device requires contact with the atrial septum throughout its entire circumference for stability. If this contact is not present or the device is undersized, it can become dislodged into the left or right atrial chamber (Fig. 31.16). The first indication that this has happened may be atrial or ventricular ectopy. Usually the device can be recaptured and repositioned or a larger device implanted. A rarer occurrence with an atrial septal occluder device is erosion of the edge of the device through the wall of the heart, resulting in an acute hemopericardium.[10] This usually occurs anteriorly and superiorly where the device is in contact with the atrial wall and aorta.[11] Symptoms are chest pain or syncope. When these occur, immediate

echocardiography and pericardiocentesis when pericardial fluid is present are mandatory (Fig. 31.5). Early pericardiocentesis may prevent low cardiac output from tamponade.

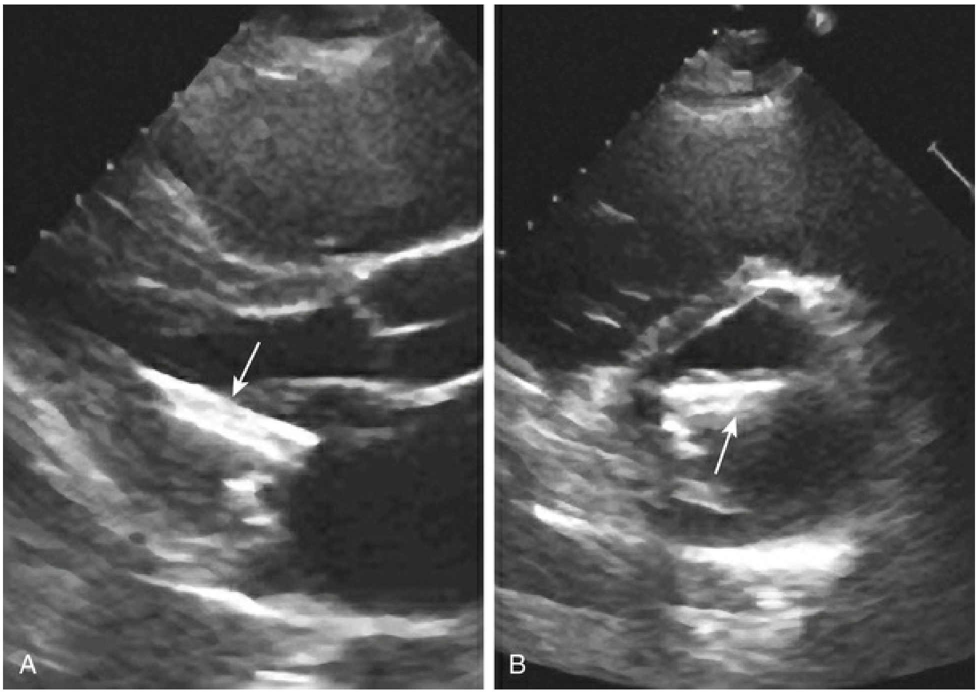

FIG. 31.16 An Amplatzer Septal Occluder device has embolized from its position in the atrial septum into the left atrium and across the mitral valve. In long axis (A) the device *(arrow)* is seen through the mitral orifice into the left ventricle. In short axis (B) the device *(arrow)* is seen sideways through the mitral orifice. Embolization of the device may be indicated by atrial and ventricular ectopy. Left in this position, the device could cause damage to the mitral valve.

Extracorporeal Membrane Oxygenation and Ventricular Assist Devices

Improved technology and miniaturization have led to increased utilization of ventricular assist devices (VADs) in children. Echocardiography provides a noninvasive method of measuring effectiveness, changes in ventricular and valve function, and complications.[12] TTE usually provides adequate images in children, but TEE may be necessary in some. Both pulsatile and continuous-flow pumps are available, including venoarterial and venovenous extracorporeal membrane oxygenation (ECMO). Cannula position is readily ascertained with 2D imaging. Effective VAD support unloads the left ventricle, which translates into decreased LV dimensions. With pulsatile VADs, device ejection is not timed to the patient's cardiac systole and maximum left ventricle end-diastolic dimension may not be synchronized with the ECG because of varying preload and afterload. The presence of a cannula in the ventricular apex may shadow this portion of the wall, and the EF may be calculated assuming an akinetic apex. The left ventricular assist device (LVAD) should decrease LV filling pressure with a consequent decrease in

pulmonary artery pressure. This should affect RV size and function, TR velocity, and IVC size. Direct calculation of RV output can be made from the RVOT time-velocity integral and diameter in most patients. Significant mitral regurgitation (MR) can indicate inadequate decompression of the left ventricle. The aortic valve usually opens intermittently with pulsatile pumps. With continuous-flow VADs, aortic valve opening depends on the patient's LV function and the pump flow. Aortic insufficiency may worsen or become continuous (Fig. 31.17). Complete aortic valve closure may lead to thrombus formation in the cardiac apex or aorta (Fig. 31.18). Cannula obstruction may occur with cannula displacement or from thrombus. Expected velocities of Doppler evaluation of cannulas in children have not been confirmed.[13]

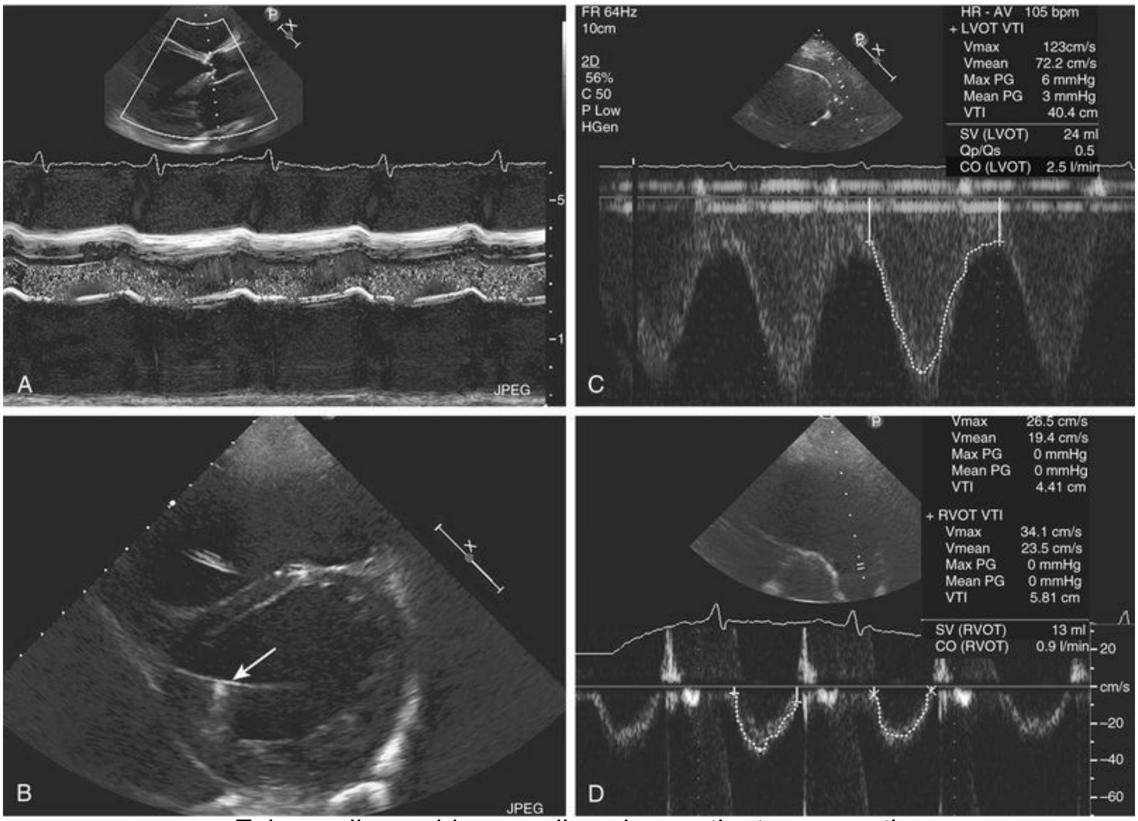

FIG. 31.17 Echocardiographic recordings in a patient on a continuous pump left ventricular assist device (LVAD). There is continuous aortic insufficiency (A) through an aortic valve that never opens. A cannula is seen entering the left ventricle *(arrow)* in B. An estimated output through the aortic cannula is made from the time velocity integral (TVI) and cannula diameter of 2.5 L/min (C). Right ventricular output is calculated from the right ventricular TVI and diameter of the right ventricular outflow tract (D) at 0.9 L/min. While calculation of LVAD output by Doppler may not be accurate with the long cannula and accelerated flow, the calculation was close to the flow from the device in this instance. It is clear that LVAD output does not equal cardiac output as aortic insufficiency is taken up by the pump and leaks back into the left ventricle, a circular shunt.

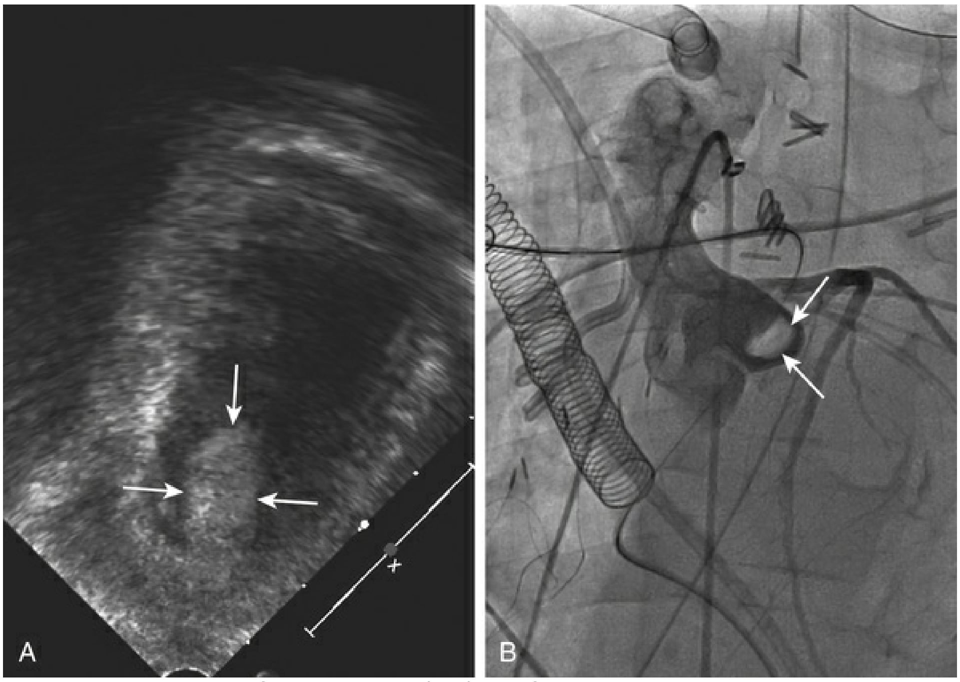

FIG. 31.18 With left ventricular (LV) dysfunction and an aortic valve that does not open on LV assist device support, thrombus may form in the left ventricular apex (A, *arrows*) or the noncoronary cusp of the aortic valve (B, *arrows*). The aortic thrombus could have been recognized on echocardiogram before cardiac catheterization.

Atrial communications may be large enough to permit right-to-left shunting and systemic desaturation and may be closed at LVAD placement or by transcatheter approach. Pericardial effusions or hematomas may occur without symptoms on LVAD support but may affect the ability to wean support. Testing a patient's ability to be weaned from LVAD support is usually accomplished by stopping or lowering VAD output while observing LV size (LVEDd) and contractility (LVEF) along with calculated LV output (from LVOT, measured time velocity integral (TVI), and diameter). These supplement the usual measurements of aortic pressure and mixed venous saturation.

Cardiovascular Communications and Physiology

The patent ductus arteriosus (PDA) and PFO are normal cardiovascular communications that may persist for variable times after birth. Echocardiography is called on particularly when the patent ductus arteriosus is implicated in slow improvement of respiratory dysfunction in premature infants. The patency of a ductus arteriosus is confirmed by Doppler detectable flow. However, the significance of its contribution to respiratory function is defined by more than the simple demonstration of patency. The PDA provides a window on the relative pulmonary and systemic pressures and resistances. This is manifested by the velocity of flow, direction of flow, and effect on distal flows.[14] When the flow velocity is less than 1.5 M/sec, the pressures in the systemic and pulmonary circulations are equal. This is not an indication of the significance of the PDA. When

pulmonary resistance is similar to systemic, the flow velocity will be low regardless of the size of the ductus. On the other hand, if the PDA is large enough, pressure will be equalized regardless of resistances. The significance of ductal shunting is reflected first by the direction of flow. Typically we think of a PDA as shunting left to right throughout the cardiac cycle. However, elevation in pulmonary vascular resistance can result in systolic right-to-left flow, with left-to-right flow only in diastole (Fig. 31.19). As pulmonary resistance falls, the systolic flow becomes more left to right. The amount of diastolic left-to-right flow through the PDA is reflected in abdominal aortic flow (Fig. 31.20). Diastolic flow reversal results from "runoff" of blood from the aorta into the pulmonary arteries. A significant PDA can then be characterized as large enough to transmit high pressure to the pulmonary arteries (≥2- to 2.5-mm diameter) and shunting left to right and thus increasing pulmonary blood flow sufficiently to produce runoff from the abdominal aorta. It is less clear that a smaller pressure restrictive PDA without enough shunt to cause abdominal aortic runoff can still negatively impact respiratory disease. Bidirectional low-velocity PDA shunting with runoff from the abdominal aorta may have a negative impact on the pulmonary circulation, but removing the pop-off by closing the PDA may also lead to suprasystemic pulmonary arterial systolic pressures. Although pulmonary resistance equal to or greater than systemic causes PDA flow to go right to left, this pattern of flow may also occur when systemic vascular resistance is less than pulmonary.

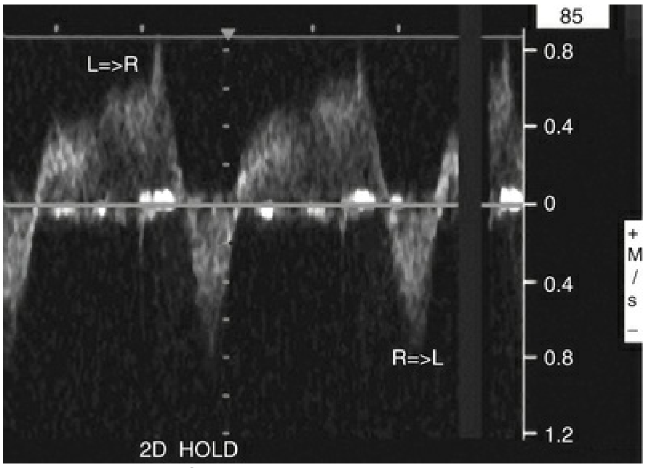

FIG. 31.19 Bidirectional flow through a patent ductus arteriosus due to elevated pulmonary vascular resistance. Systolic flow is right to left (R = >L) while diastolic flow is left to right (L = >R).

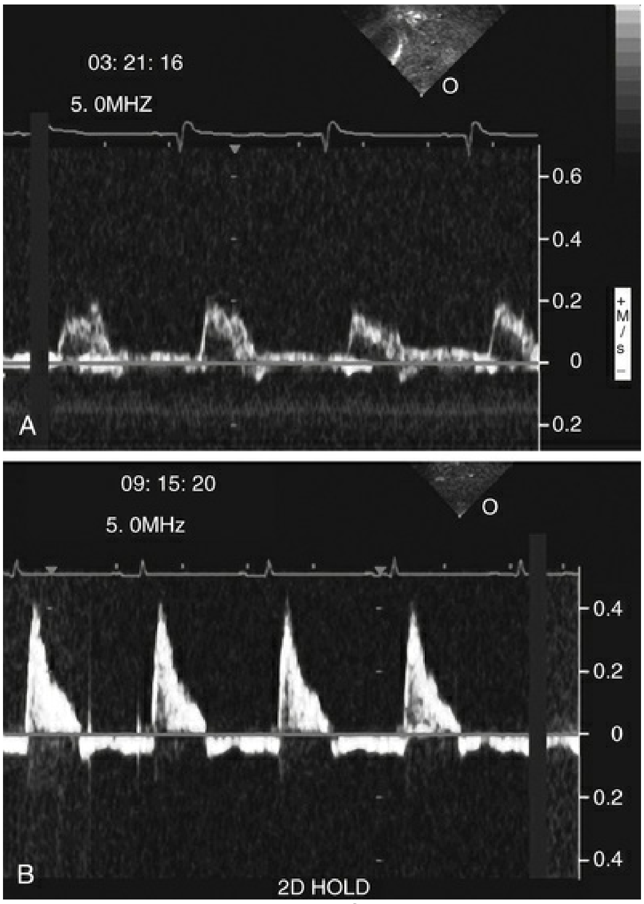

FIG. 31.20 Normal abdominal aortic flow is antegrade throughout the cardiac cycle except for an early diastolic reversal (A). When there is a patent ductus arteriosus and subsystemic pulmonary resistance, there is diastolic reversal of flow (B) as blood runs into the pulmonary circulation in diastole.

This is further illustrated in the presence of an arteriovenous malformation in an infant (great vein of Galen or hepatic). In this circumstance, pulmonary resistance exceeds systemic resistance because of the low-resistance arteriovenous malformation. Ductal flow is right to left throughout the cardiac cycle, while there is “runoff” from the abdominal aorta also toward the malformation (Fig. 31.21).

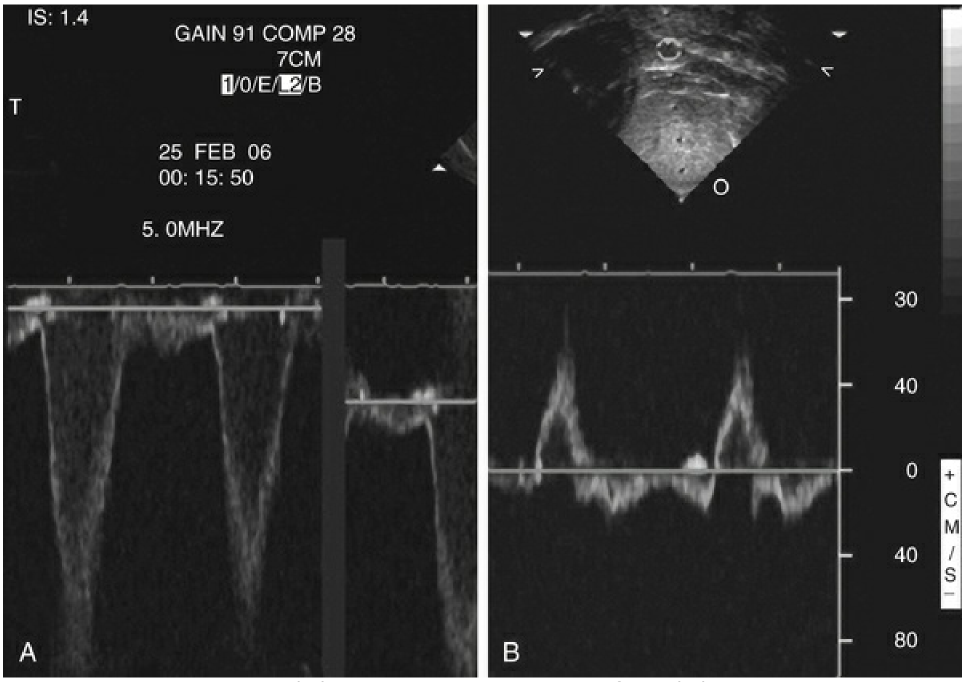

FIG. 31.21 Ductal (A) and abdominal aortic flow (B) with a cerebral arteriovenous malformation. Because systemic resistance is low, flow is continuously right to left through the ductus. But diastolic aortic flow runs toward the cerebral arteriovenous malformation in diastole. Were aortic runoff due to subsystemic pulmonary resistance, ductal flow would be left to right in diastole.

Finally, left-sided obstructive lesions such as hypoplastic left heart, critical aortic stenosis, or preductal coarctation of the aorta may also produce systolic right-to-left flow through a PDA, even if pulmonary resistance is subsystemic. Nature abhors a vacuum, and with inadequate blood flow to the systemic circulation, blood will flow right to left across the PDA to fill the void.

The PFO provides a similar window on the relative pressures and compliances of the right and left atria. There is often Doppler-detectable left-to-right flow in the valve component of the PFO until the communication seals, and the velocity allows determination of the pressure difference between right and left atria using the simplified Bernoulli equation ($P = 4 \times V^2$) (Fig. 31.22). Under normal conditions the pressure differences are small, and the velocity of the left-to-right shunt is less than 1.5 M/sec. LV diastolic dysfunction and mitral valve disease lead to elevated left atrial pressures, and a peak and mean pressure gradient between the atria can be calculated. Assuming a normal right atrial pressure, or when the right atrial pressure is directly measured in the ICU, absolute left atrial pressure can also be calculated. This supplements the assessment of mitral regurgitation by color flow Doppler and mitral stenosis from the diastolic velocity measured across the mitral valve. When right atrial pressure is elevated, with poor right ventricular compliance (due to myocardial issues or absolute volume, significant tricuspid regurgitation, or stenosis), a right-to-left shunt can be observed. With tricuspid or mitral atresia, the velocity of flow across the atrial septum adds to imaging in assessing the adequacy of the communication.

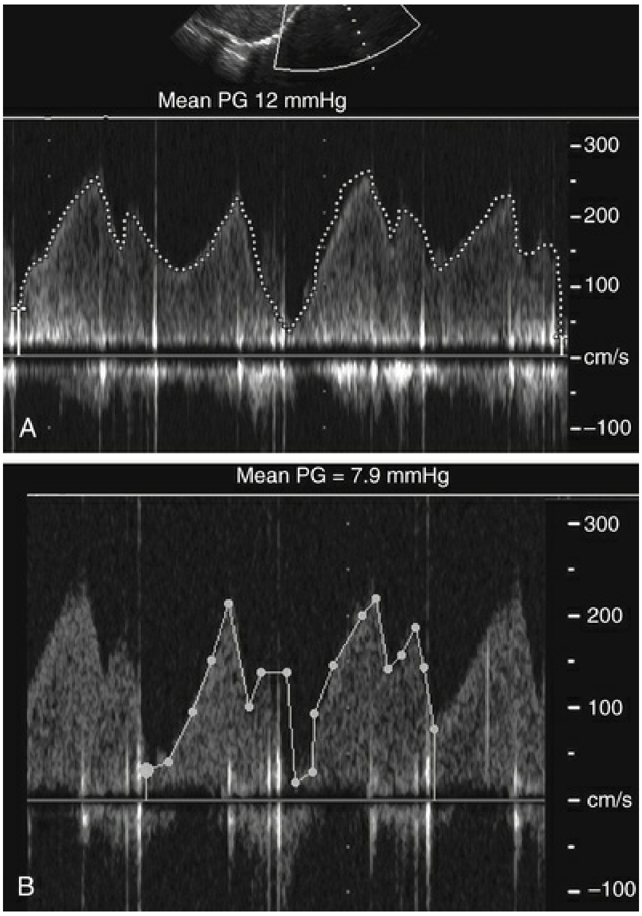

FIG. 31.22 Recordings of flow across an atrial communication in a patient with left ventricular hypoplasia and a "left ventricular growth" operation. There is significant diastolic restriction to flow. In A, a 12-mm Hg gradient between the right and left atria is calculated from the left-to-right atrial flow. After diuresis in B, the calculated pressure difference falls to 7.9 mm Hg, although the peak velocities are similar. Noninvasive measurement of atrial flow allows calculation of changes in hemodynamic state.

A VSD can also give information about relative ventricular pressures and outflow resistances. Low-velocity systolic left-to-right shunt confirms systemic right ventricular and pulmonary artery systolic pressures when there is no right ventricular outflow obstruction. When the defect is tiny and pulmonary resistance low, the left-to-right shunt is high velocity. A moderate-sized VSD that is pressure restrictive but allows a "large" left-to-right shunt that produces left heart enlargement may show a high-velocity systolic shunt but also a pandiastolic left-to-right shunt because of LV volume overload (Fig. 31.23). An artificial but clinically useful application of this is the acute change in ventricular shunting demonstrated by Doppler during placement or adjustment of a surgically placed pulmonary arterial band. Not only are the diameter of the band from 2D imaging and the gradient across the band from Doppler seen but also the change in flow pattern across the VSD, which can become bidirectional. This can be evaluated in the operating room with TEE or once the patient returns to the ICU.

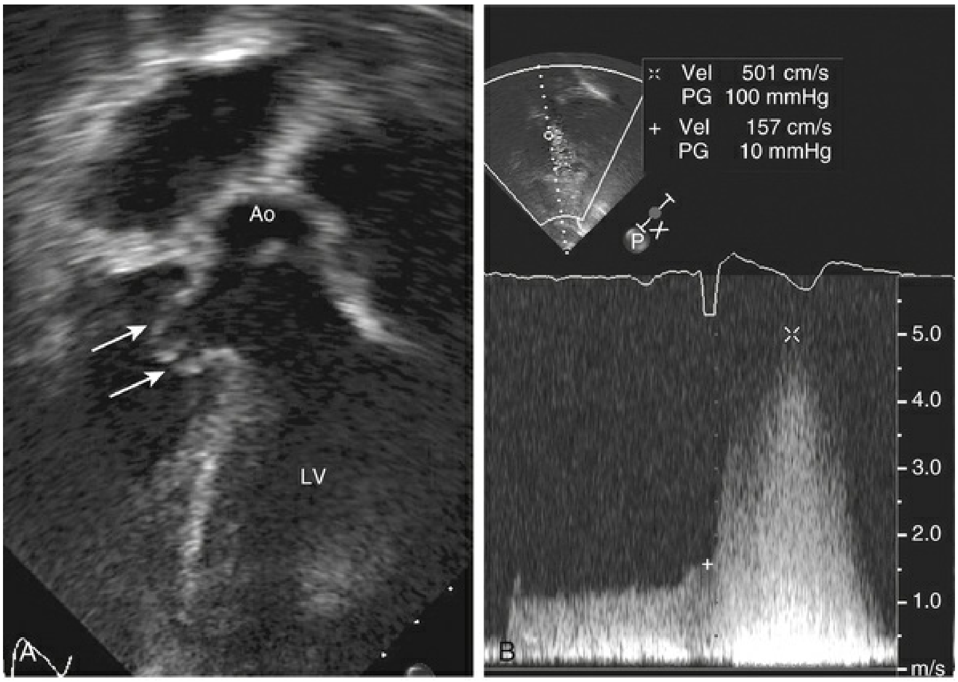

FIG. 31.23 Echocardiographic recordings from a patient with a moderate-sized perimembranous ventricular septal defect. *Arrows* point to the aneurysm of the atrial septum between the left ventricle *(LV)* and aorta *(Ao)* in Panel A from an apical five-chamber view. Doppler recorded from the left-to-right shunt in B shows a large systolic pressure difference between right and left ventricles. There is continuous diastolic left-to-right flow with velocities suggesting a 5- to 10-mm Hg pressure difference, presumably from a "large" left-to-right shunt with left ventricular enlargement and increased left ventricular diastolic pressures.

Summary

Echocardiography is often thought of as a diagnostic technique that reveals the anatomy and function of the heart and, occasionally, the presence of a pericardial effusion. However, there are many other occasions where it can provide assistance to the pediatric or neonatal intensivist, cardiologist, and cardiovascular surgeon in day-to-day management of ICU patients through evaluation of therapy or defining changing hemodynamics and physiology to assess medical therapy. Surveillance evaluation may detect changes before they become clinically apparent. It may be better to remove the occasional normal appendix—get an echocardiogram when no new information is obtained—than to overlook an unexpected alteration in condition that precedes clinical change. The noninvasive nature that does not impact the patient by transport or alter the clinical condition being observed makes echocardiography a primary management tool for the ICU patient.

CHAPTER 32

Diagnostic and Therapeutic Cardiac Catheterization

Alan W. Nugent

PEARLS

- The cardiac catheterization laboratory plays important diagnostic and therapeutic roles in the management of children in the pediatric intensive care unit.
- For patients with cardiac disease whose critical care course is not progressing as expected, early exploration for diagnosis of unsuspected or residual defects by cardiac catheterization often improves outcomes.
- To maximize the utility of catheterization, effective communication between the intensive care physician and the interventional cardiologist is essential.

The cardiac catheterization laboratory plays an important diagnostic and therapeutic role in the management of children in the critical care environment. Obtaining comprehensive hemodynamic data and angiography in the catheterization laboratory helps formulate and tailor management strategies. In the postoperative cardiac patient, the diagnosis of unsuspected or residual anatomic defects may enable therapeutic surgical or catheter-directed interventions to improve a patient's outcome. Numerous interventions can be performed during cardiac catheterization. The pediatric critical team must be aware of the possible benefits and limitations of catheterization procedures, and effective communication between the intensive care physician and the physician performing the procedure is crucial.

Catheterization Laboratory Environment

Cardiac catheterization laboratories are remote from the ICU and rarely are configured to accommodate critical care personnel and equipment. Relative to

patient size, the biplane fluoroscopic equipment used for imaging is in close proximity to the patient's head and neck, limiting access to the airway. A mechanical ventilator and monitors around the patient further confine space and limit access to the patient during a procedure. In addition, the environment is darkened to facilitate viewing of images, and full monitoring, either invasive or noninvasive, must be established before the procedure begins. Because of limited access to the patient and airway, end-tidal capnography and pulse oximetry are mandatory to ensure adequate ventilation and oxygenation during the procedure and to provide immediate detection of disconnection or dislodgment of the endotracheal tube that could inadvertently occur underneath sterile drapes. The environment is cooler because of computer and x-ray equipment, and without focus and monitoring of temperature, children may become hypothermic from conductive and convective heat loss; this is a particular problem in neonates and infants. In addition, frequent flushing of the catheters and sheaths contributes to hypothermia. Unnecessary exposure of the child must be prevented and convective warming blankets used where possible. Care must be taken when positioning a patient on the catheterization table because of the risk to pressure areas and of nerve traction injury. In particular, brachial plexus injury may occur when the patient's arms are positioned above the head for prolonged periods to enable better exposure for the lateral camera. To facilitate femoral vein and arterial access, the pelvis is commonly elevated from the catheterization table. This position may displace abdominal contents cephalad, restricting diaphragm excursion and increasing the risk for respiratory depression in a sedated patient.

Safe transportation of a critically ill child from the ICU to the catheterization laboratory can be a significant challenge but should not be a deciding factor as to whether or not the procedure should be performed. Safe transport requires planning and multidisciplinary coordination. This process includes physician and nursing staff accompanying the patient with complete monitoring and resuscitation equipment, respiratory therapy staff to assist with ventilation and establishing mechanical ventilation in the catheterization laboratory if indicated, coordinating timing with the laboratory staff to prevent needless delays, assistance with establishing adequate space for equipment and patient access in the laboratory, and correct positioning on the catheterization table to enable access for both the cardiologist and intensive care staff, as needed.

Adequate sedation and anesthesia during cardiac catheterization are essential to facilitate acquisition of meaningful hemodynamic data and to facilitate interventional procedures. For the most part, hemodynamic or diagnostic catheterization procedures can be performed with the patient under sedation.[1] For many interventional procedures, sedation may be appropriate; however, for procedures that are associated with significant hemodynamic compromise or are prolonged, general anesthesia is preferable. Whatever technique is used, hemodynamic data must be attained in conditions as close to normal as possible. For accurate calculation of the intracardiac shunt, reducing the inspired oxygen concentration to room air may be necessary, although this step may be inadvisable in patients with significant pulmonary vein desaturation and lung injury.

Hemodynamic and Oxygen Saturation Data

Hemodynamic cardiac catheterization is often unnecessary when echocardiographic analysis with Doppler measurements and color flow mapping is complete and unambiguous. However, in patients with complex cardiac anatomy, severe low cardiac output state, pulmonary hypertension, severe lung injury of uncertain etiology, or with concerns for important residual anatomic lesions after cardiac surgery, physiologic data from catheterization may provide important information.[2] Catheterization allows description of the direction, magnitude, and approximate location of intracardiac and intrapulmonary shunts. Intracardiac and intravascular pressures are measured to determine the presence of obstructions and whether shunt orifices are restrictive or nonrestrictive. Pressure gradients across sites of obstruction must be considered in light of estimated cardiac output, as a small pressure gradient measured at a time of low cardiac output is misleading.

Normally, no significant change in oxygen saturation from venae cavae to pulmonary artery is observed. In the child with congenital heart disease, the superior vena cava provides the simplest mixed venous oxygen saturation. A greater than 5% to 10% increase in oxygen saturation from the superior vena cava through to the pulmonary artery suggests the presence of a left-to-right shunt at the level of the right atrium with an atrial septal defect (ASD), in the right ventricle (RV) with a ventricular septal defect (VSD), and in the pulmonary artery with a patent ductus arteriosus (PDA) or aorto-pulmonary artery collateral vessels.[3] The magnitude of the left-to-right shunt can be calculated by applying the Fick equation to the pulmonary and systemic vascular beds separately:

$$Qp = VO_2/(SpvO_2 - SpaO_2)(Hb)(1.36)(10) \qquad \textbf{Eq. 32.1}$$

$$Qs = VO_2/(SaO_2 - SsvcO_2)(Hb)(1.36)(10) \qquad \textbf{Eq. 32.2}$$

where *Qp* is pulmonary blood flow, *Qs* is systemic blood flow, VO_2 is oxygen consumption, $SpvO_2$ is pulmonary vein saturation, $SpaO_2$ is pulmonary artery saturation, SaO_2 is arterial oxygen saturation, $SsvcO_2$ is superior vena cava oxygen saturation, and *Hb* is hemoglobin. (Note that saturation data in the equations is expressed as a decimal number and not as a percentage, eg, 98% saturation = 0.98.)

In pediatric patients, the pulmonary and systemic flows usually are indexed to body surface area:

$$CI = Qs/BSA \qquad \textbf{Eq. 32.3}$$

where *CI* is cardiac index and *BSA* is body surface area.

Thermodilution can be used to calculate the cardiac output in pediatric patients, although it is confounded by the presence of intracardiac or extracardiac shunts.[4] Measurement of oxygen consumption is preferable[5] because assumed values are unreliable in patients with critical illness and in those requiring substantial hemodynamic support. The practical reality is that many catheterization laboratories assume oxygen consumption,[6] especially in neonates and infants. Thus with the

numerator assumed, the inherent error of all calculations should always be considered, particularly with respect to flow and resistance calculations. A common error is to be unaware that the oxygen consumption tables commonly used are already indexed to BSA, and indexing a second time is a mistake.

The pulmonary to systemic blood flow ratio (Qp/Qs) can be derived simply from the measured oxygen saturation values because all other variables cancel out (from Equations 32.1 and 32.2):

$$Qp/Qs = (SaO_2 - SsvcO_2)/(SpvO_2 - SpaO_2) \qquad \textbf{Eq. 32.4}$$

The patient whose aortic blood is fully saturated can be assumed to have no significant right-to-left intracardiac shunt. However, when a right-to-left shunt is present, oxygen saturations also should be obtained from the pulmonary veins, left atrium, and left ventricle to determine the source of desaturated blood. Pulmonary venous desaturation implies a primary pulmonary source of venous admixture (eg, pneumonia, atelectasis, or other pulmonary disease).

Vascular resistance is calculated by the change in pressure divided by the flow (Dp/Q):

$$\text{Pulmonary vascular resistance (PVR)} = (\text{MeanPAP} - \text{MeanLAP})/Qp \qquad \textbf{Eq. 32.5}$$

$$\text{Systemic vascular resistance (SVR)} = (\text{MeanAoP} - \text{MeanSVCP})/Qs \qquad \textbf{Eq. 32.6}$$

where *PAP* is pulmonary artery pressure, *LAP* is left atrial pressure, *AoP* is aortic pressure, *SVCP* is superior vena cava pressure, *Qp* is pulmonary blood flow, and *Qs* is systemic blood flow.

Once again for pediatric patients, the vascular resistance is usually indexed to body surface area and expressed as Wood units.m^2:

$$\text{PVR} = (\text{MeanPAP} - \text{MeanLAP})(\text{BSA})/Qp \qquad \textbf{Eq. 32.7}$$

$$\text{SVR} = (\text{MeanAoP} - \text{MeanSVCP})(\text{BSA})/Qs \qquad \textbf{Eq. 32.8}$$

Assessment of Critical Illness

The cardiac catheterization laboratory can be useful in a number of situations during the management of critically ill infants and children who have structurally normal hearts (Table 32.1) or congenital heart disease. Fluoroscopy can be used to assist with placing difficult central venous or pulmonary artery lines, performing

pericardiocentesis and pleurocentesis, and assessing diaphragm function.

TABLE 32.1

Indications for Cardiac Catheterization or Management in the Catheterization Laboratory of Pediatric Intensive Care Patients with Noncongenital Heart Disease

Diagnostic	Hemodynamic evaluation of intracardiac and intravascular pressures and oxygen saturations Evaluation of persistent hypoxemia: Pulmonary vein desaturation Decreased pulmonary blood flow Intracardiac right-to-left shunt Cardiac output measurement Pulmonary hypertension assessment and reactivity Fluoroscopy: Central venous catheter position Diaphragm movement Myocardial biopsy
Therapeutic	Pericardiocentesis Pleurocentesis Radiofrequency catheter ablation of an arrhythmogenic focus

Patients with pulmonary hypertension can benefit from catheterization to diagnose or rule out structural disease involving the pulmonary arteries or pulmonary veins, as in cases of multiple thromboembolic disease or undiagnosed pulmonary vein stenosis. Acute vasoreactivity testing is important for evaluation of the response of pulmonary vasculature to vasodilator treatment, for example, with increased FiO_2 or inhaled nitric oxide.[7] Such evaluation and measurement of a specific response is important for prognostication and longer-term management strategies of patients with pulmonary hypertension. In the presence of structural heart disease with a left-to-right shunt and elevated PVR, pressure and saturation measurements are often repeated with pulmonary vasodilators to assess both the reactivity of the pulmonary vascular bed and any contribution of ventilation/perfusion abnormalities to hypoxemia. If breathing 100% oxygen and inhaled nitric oxide increases pulmonary blood flow and dramatically increases Qp/Qs (with a fall in PVR), potentially reversible processes such as hypoxic pulmonary vasoconstriction may be contributing to the elevated PVR. The patient with a high, unresponsive PVR and a small left-to-right shunt may have extensive pulmonary vascular damage from the underlying lung injury or irreversible obstructive pulmonary vascular disease.

The reactivity of the pulmonary vascular bed and change in PVR are important components to the assessment of patients potentially listed for cardiac transplantation. An elevated PVR or pulmonary artery pressure is a risk factor for cardiac transplantation.[8] In patients with heart failure, left atrial hypertension can be a potent cause of elevated PVR. However, if PVR decreases with 100% FiO_2/inhaled nitric oxide during pretransplant catheterization, they still may be suitable candidates for cardiac transplantation.

Patients who present with severe cardiac failure because of myocarditis, idiopathic dilated cardiomyopathy, or intractable dysrhythmias often require cardiac catheterization, not only for hemodynamic assessment but also for endomyocardial biopsy. Biopsies in these circumstances can be associated with significant morbidity, and treatment of the baseline condition should not be delayed until catheterization is performed.[9] The risk of myocardial perforation is particularly increased in infants with thin-walled ventricles, and biopsies are generally contraindicated in infants

with a very dilated and poorly functioning left ventricle. Patients who have a low cardiac output state associated with fulminant myocarditis are at risk for dysrhythmias during catheterization, and resuscitation resources must be immediately available, including mechanical support. The goal of biopsy is to firmly establish a diagnosis (thus management plan and prognosis). Although important, biopsy must not take priority over efforts to support the circulation and maintain cardiac output.

Transcatheter Radiofrequency Ablation

Pediatric patients undergoing radiofrequency catheter ablation (RFCA) vary in age and diagnosis.[10] Ablation may be indicated in newborns or infants with persistent reentrant tachycardia or ectopic atrial tachycardia[11,12] and in older children with ectopic foci but otherwise structurally normal hearts that are refractory to or poorly controlled by conventional antiarrhythmic drugs. If an incessant dysrhythmia, particularly a supraventricular tachycardia such as ectopic atrial tachycardia or permanent junctional reciprocating tachycardia, is the primary cause of a dilated poorly contracting heart at the time of presentation, electrophysiologic study and mapping of the dysrhythmia focus may be important diagnostic steps performed in the catheterization laboratory. Elective mechanical support of the circulation with extracorporeal membrane oxygenation (ECMO) may be indicated in order to preserve hemodynamic stability during ablation.[13] Successful RFCA in this circumstance may enable recovery of ventricular function.[14]

An increasing population of patients undergoing ablation consists of those with previous surgical repair of congenital heart defects. Patients with persistent volume or pressure load on the right atrium and those who required an extensive incision and suture lines within the right atrium, such as following a Mustard, Senning, or Fontan procedure, may be at increased risk for supraventricular tachyarrhythmias such as atrial flutter and fibrillation.[15,16] Ventricular tachyarrhythmias may develop late after repair of certain congenital heart defects, such as right ventricular outflow tract reconstruction for tetralogy of Fallot.[17]

RFCA procedures can be lengthy. Because children find it difficult to lie still for prolonged procedures, endotracheal general anesthesia is usually preferred. In addition, patients must remain immobile to prevent catheter movement at the time of ablation, because sudden patient movement may result in creation of a radiofrequency lesion at an incorrect site. For instance, if the focus is close to the atrioventricular (AV) node, inadvertent movement might displace the catheter and cause permanent AV conduction blockade.

On occasion, holding ventilation in either inspiration or expiration may be necessary to eliminate all movement and ensure adequate contact of the ablation catheter with the arrhythmic focus. For the most part, RFCA procedures are well tolerated hemodynamically and blood loss is minimal. During mapping, the focus is stimulated and the tachyarrhythmia induced. This situation may result in hypotension but usually is short-lived and can be readily converted via intracardiac pacing. If hypotension is prolonged and intracardiac conversion is unsuccessful, transthoracic cardioversion may be necessary; therefore a defibrillator should be immediately available.

Congenital Heart Disease

Although most congenital heart defects can be evaluated noninvasively by echocardiography, computed topography, or magnetic resonance imaging, further preoperative evaluation by angiography is essential in selected instances to assist with surgical planning.

Patients with pulmonary atresia and intact ventricular septum (PA/IVS) require careful examination of the coronary anatomy before decompressing the RV, either surgically or with catheterization techniques, because of the possible presence of RV-dependent coronary circulation (RVDCC).[18] RV to coronary artery fistulas can be seen on echocardiography, but selective right ventricular angiography, aortography, or selective coronary angiography is important to determine any associated coronary stenoses or atresia to diagnose RVDCC. If coronary perfusion is dependent on the high-pressure RV, myocardial ischemia will occur if the right ventricle is decompressed. Besides coronary artery lesions, a catheterization may be necessary to selectively image aortopulmonary collaterals in tetralogy of Fallot and pulmonary atresia with diminutive native pulmonary arteries. Angiography can delineate the exact location and anatomy of these collaterals and may be followed by coil occlusion if there is dual supply to the native pulmonary arteries. It is important to know the extent of collateral vessels before surgery and cardiopulmonary bypass because of the risk for impaired systemic perfusion from excessive runoff to the pulmonary circulation.

Patients with hypoplastic left heart syndrome with mitral stenosis and aortic atresia (MS/AA) may also be at higher risk for early mortality after stage 1 palliation with the Norwood procedure.[19] Analogous to the PA/IVS patient population, patients with MS/AA may have left ventricle–subepicardial coronary artery fistulae and be at risk for inadequate myocardial protection during cardiopulmonary bypass and ischemia following stage 1 palliation. Preoperative coronary angiography may also be warranted in this subgroup before surgical palliation.[20] Finally, preoperative angiography may be useful in patients with obstructed total anomalous pulmonary venous connection (TAPVC). Although pulmonary venous anatomy can often be determined by noninvasive methods, palliative transcatheter approaches to relief of pulmonary venous obstruction may be lifesaving in the critically ill neonate[21] and permit surgical repair when the patient is in much better overall condition.

Therapeutic Interventions in the Newborn

Interventional cardiac catheterization continues to evolve. Many specific anatomic defects can be treated in the catheterization laboratory to alleviate the need for surgical intervention.

Atrial Communication Procedures

The first therapeutic procedure performed in the catheterization laboratory for congenital heart disease was balloon atrial septostomy (BAS) in newborns diagnosed with transposition of the great arteries (TGAs) with intact ventricular septum.[22] A BAS is usually necessary in newborns with TGAs to facilitate mixing of systemic and pulmonary venous return at the atrial level before the arterial switch operation. This procedure can be performed with echocardiographic guidance[23] (Fig. 32.1) or in the

cardiac catheterization laboratory if additional diagnostic information is required or there are potential vascular access problems. Via either the femoral or umbilical vein, a balloon catheter is advanced across the atrial defect from right atrium to left atrium and rapidly jerked back to the right atrium to tear the septum primum. It is always preferable to facilitate mixing at the atrial level and reduce left atrial pressure and risk for pulmonary hypertension before the arterial switch procedure. Although it has been reported that BAS may be associated with an increased risk for embolic neurologic injury,[24] this has not been the experience at the majority of institutions.[25,26] Whatever the mode of imaging, once access is obtained, anticoagulation with heparin can be administered theoretically to reduce the risk of thromboembolism.

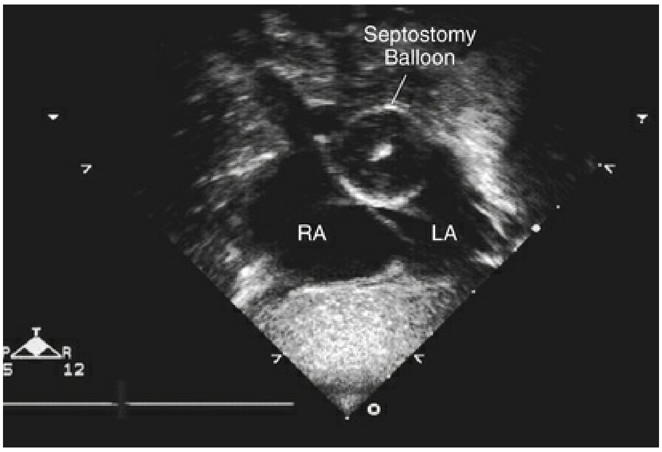

FIG. 32.1 Echocardiography-guided balloon atrial septostomy. From the subcostal view, the septostomy balloon is easily seen as it inflates in the left atrium (LA). *RA*, Right atrium.

In some patients with a single-ventricle lesion (such as mitral atresia or hypoplastic left heart syndrome) and a restrictive or near intact atrial septum, the left atrial pressure may be high at birth, causing pulmonary edema and pulmonary artery hypertension. The physiology in this circumstance is identical to that of patients with obstructed TAPVC. Patients are usually cyanotic and acidotic with a low cardiac output state. Survival is not possible without urgent left atrial decompression.[27] It is important to appreciate that the atrial septum is often thickened in these patients, which is quite different from the thin-walled restrictive foramen ovale of patients with TGA. Because of its thickness, disruption of the septum using a balloon atrial septostomy technique is not usually possible. In addition to the thickened atrial septum, the atrial cavity size usually is too small to even accommodate a septostomy balloon. Instead, decompression of the pulmonary atrium can be achieved with a Brockenbrough transseptal puncture (Fig. 32.2A) or radiofrequency perforation, followed by an atrial septoplasty involving balloon dilation and often stent placement across the thickened atrial septum (Fig. 32.2B). These infants are critically ill even with uncomplicated procedures. Because of the degree of cyanosis and the low cardiac output state, concurrent resuscitation with volume replacement, inotropic support, and mechanical ventilation are usually necessary during this procedure until adequate mixing is established and pulmonary veins are decompressed. In high-risk, single-ventricle neonates a more recent strategy has been the surgical use of bilateral PA bands to protect the pulmonary

vascular bed and promote systemic output.[28] The same philosophy has been applied to optimize the preoperative status of hypoplastic left heart syndrome with intact atrial septum after successful left atrial decompression in the catheterization laboratory.[29]

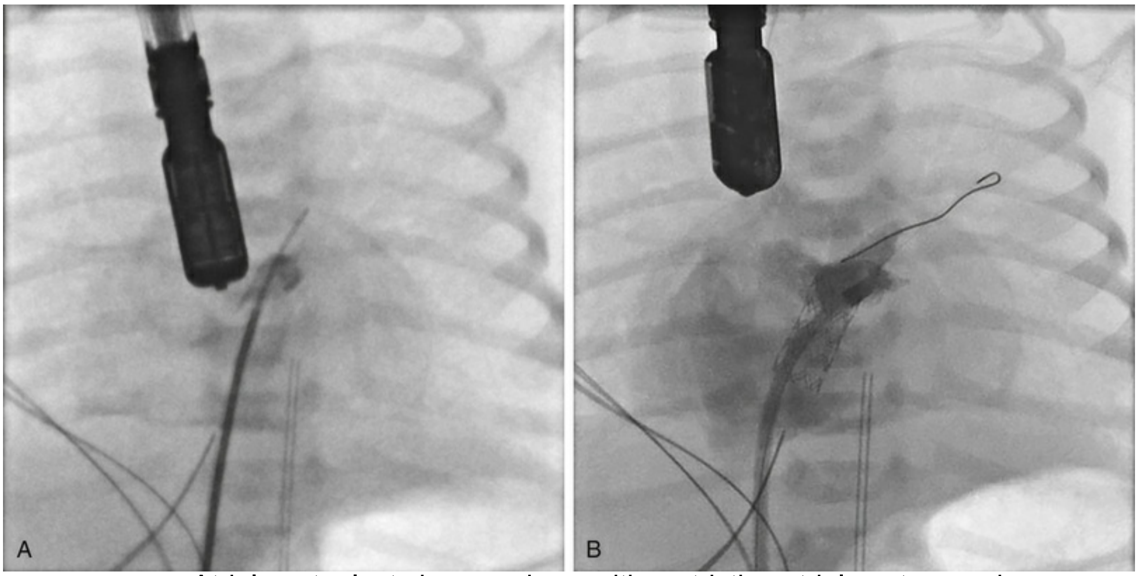

FIG. 32.2 Atrial septoplasty in a newborn with restrictive atrial septum and hypoplastic left heart syndrome. Note the severe pulmonary edema. (A) View of a Brockenbrough transseptal needle introduced across a stained thickened atrial septum. (B) Anteroposterior view following stent placement across the thickened atrial septum. Contrast is seen equally in both the hypoplastic left atrium and the right atrium.

Pulmonary Balloon Valvotomy

Congenital pulmonary valve stenosis may present as a murmur heard in the newborn period. If the obstruction is mild, intervention with balloon dilation can be deferred. Newborns with critical pulmonary valve stenosis or pulmonary valve atresia have severe restriction or absence of antegrade flow across the right ventricular outflow and, as a result, have ductus arteriosus-dependent pulmonary blood flow. Balloon dilation in the catheterization laboratory is the therapeutic procedure of choice (Fig. 32.3).[30] A balloon catheter is passed over a guidewire antegrade across the pulmonary valve, and balloon dilation, usually to approximately 120% size of the pulmonary valve annulus, is performed. Heart block and ventricular ectopy may occur with wire manipulation in the RV but are usually transient. Antegrade flow across the pulmonary valve may not increase significantly after balloon dilation until right ventricular compliance improves, and continuation of prostaglandin E1 (PGE1) infusion to maintain patency of the ductus arteriosus for several days following balloon dilation may be necessary. For some patients longer-term supplemental pulmonary blood flow is necessary, and this can be achieved with a PDA stent or surgical shunt. Perforation of the relatively thin right ventricular outflow tract with the guidewire is a potential complication, particularly in low-birth-weight and premature newborns.

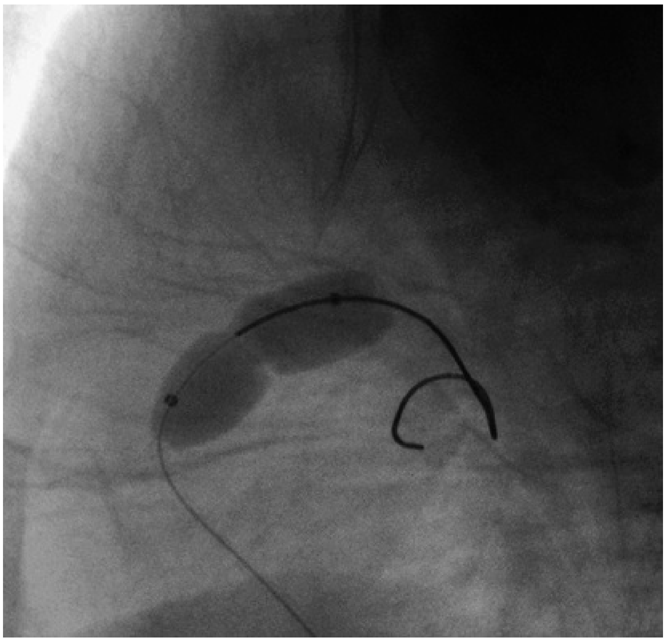

FIG. 32.3 Pulmonary valvuloplasty in a newborn with severe pulmonary valve stenosis. Lateral view with balloon catheter centered across a stenotic pulmonary valve. As the balloon is inflated, a “waist” representing the stenotic valve is seen.

Aortic Balloon Valvotomy

The newborn with critical valvar aortic stenosis who develops hypotension and acidosis as the ductus arteriosus closes (ductal dependent systemic blood flow) requires resuscitation with PGE1 to restore aortic flow, plus mechanical ventilation and inotropic support to achieve stabilization before an intervention is performed. Balloon dilation of the stenotic aortic valve during cardiac catheterization is the preferred intervention (Fig. 32.4),[31] although surgical valvotomy under direct vision using cardiopulmonary bypass (CPB) is the surgical alternative.[32] At catheterization, a guidewire is passed either retrograde (via femoral/carotid artery) or antegrade (via femoral or umbilical vein) across the aortic valve. A balloon catheter is passed over the wire, and serial dilations are performed up to 90% to 100% size of the aortic valve annulus. The pressure gradient across the aortic valve is remeasured after each dilation, and an ascending aortogram is obtained to evaluate aortic valve regurgitation. Because of the initial minimal flow across the valve, balloon dilation of critical neonatal aortic stenosis is usually well tolerated. Despite the successful relief of obstruction, antegrade flow across the valve may not increase significantly until left ventricular compliance and function improve; therefore continuation of PGE1 infusion, mechanical ventilation, and vasoactive drugs following dilation for some days may be necessary. Until flow across the valve increases, the residual gradient across the aortic valve will be underestimated by echocardiography, and serial studies usually are necessary to track the evolving gradient as left ventricular function improves. Other complications include possible mitral valve damage from either an antegrade or retrograde approach, ventricular fibrillation, and an acute low cardiac output state secondary to coronary ischemia in patients with a hypertrophied ventricle.

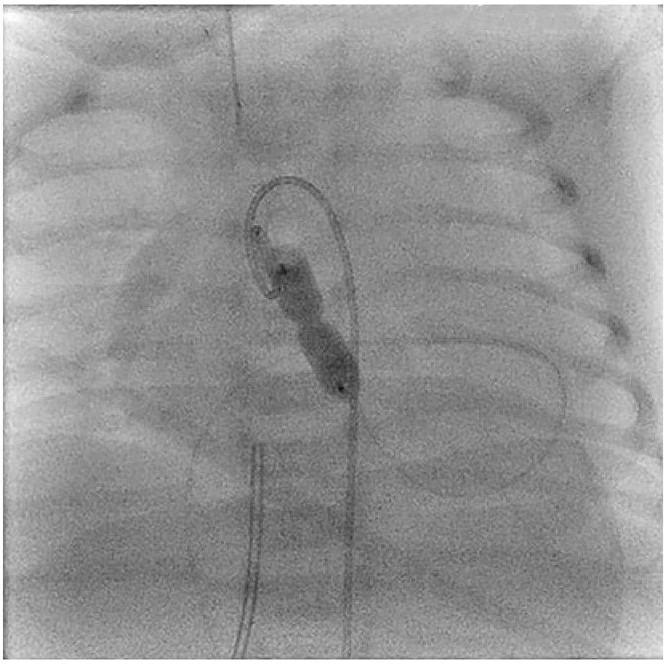

FIG. 32.4 Aortic valvuloplasty in a newborn with critical aortic stenosis. Anteroposterior view with antegrade catheter course from the femoral vein. The balloon, also with the "waist" apparent, is seen being inflated across the aortic valve.

Perioperative Interventional Procedures

A thorough understanding of the anatomy and morphology of complex congenital heart defects is essential for successful management of patients with complex congenital heart disease. This is particularly critical when establishing a diagnosis and planning surgical intervention. Important for the successful perioperative management in the ICU is a thorough understanding of the pathophysiology of various defects. This understanding includes not only the preoperative pathophysiology associated with defects but also the potential alteration in pathophysiology related to surgical repair and/or development of complications in the postoperative period. As a general guide, if patients are not progressing as expected and low cardiac output persists, early cardiac catheterization should be performed to investigate and exclude the possibility of undiagnosed or residual structural defects. Despite biases to the contrary, early postoperative catheterization can be performed with no significant increased risk of adverse events.[33]

Scheduled Interventional Procedures

Transcatheter treatment of congenital cardiac defects continues to evolve and expand and, in some circumstances, is effectively replacing the need for conventional intraoperative surgical procedures.[34] For example, several centers are routinely palliating hypoplastic left heart syndrome with a hybrid approach including transcatheter-based ductal stent, along with bilateral pulmonary artery bands and balloon atrial septostomy, with favorable early results.[35] Transcatheter pulmonary valves have been successfully inserted in patients with right ventricular outflow tract conduit dysfunction.[36] Ductal dependent pulmonary blood flow lesions

can now be treated with a PDA stent, in place of a Blalock-Taussig (BT) shunt. The impetus for the increasing numbers of PDA stent procedures is partly related to surgical morbidity but importantly due to technical advances in coronary artery stents, enabling low profile and ease of delivery in newborns.[37] Additional interventions now routinely performed in the catheterization laboratory include angioplasty, often combined with transcatheter placement of endovascular stents, for treatment of systemic and pulmonary arterial and venous stenoses, and device occlusion or embolization of systemic-to-pulmonary arterial communications, venous channels, fistulas, muscular VSDs, ASDs, and PDAs.

Risks and Complications

Placement of catheters in and through the heart increases the risk for dysrhythmias, perforation of the myocardium, damage to valve leaflets and chordae, cerebral vascular accidents, and air embolism. Use of radiopaque contrast material may cause an acute allergic reaction (rare in children with the use of nonionic contrast media), pulmonary hypertension, acute kidney injury, and myocardial depression. Blood loss may be sudden and unexpected when large-bore catheters are used or vessels are ruptured. More insidious blood loss may occur over several hours in heparinized small children or neonates because of bleeding around the catheter site or multiple aspirations and flushes of catheters. Transfusion requirements and appropriate vascular access should be continually assessed.

Arrhythmias, albeit transient, may be recurrent and even fatal if not promptly treated. Arrhythmias include catheter-induced supraventricular tachycardias, ventricular tachycardia, ventricular fibrillation, and occasionally complete heart block requiring temporary transvenous pacing. On most occasions, removing the wire or catheter resolves the arrhythmia, but full resuscitation and cardioversion equipment must be available in case the arrhythmia does not resolve.

The complications of various interventional procedures are related in part to the type of procedure, but all share the risks associated with percutaneous vascular access with large catheters that course through the heart and vessels.[38] Table 32.2 lists the specific problems that can occur during various transcatheter procedures. The pediatric catheterization community has matured in respect to quality improvement initiatives. There are now multiple prospective registries that shed more light on modern catheterization and the associated risks. This includes the IMPACT Registry with large participation.[39] And a smaller but more complex multicenter group has reported overall adverse event (AE) rates in the range of 5% to 18%, with higher AE rates reported in interventional (20%) versus noninterventional (10%) catheterization procedures.[40] This group has been able to develop a risk adjustment model that should allow comparisons of adverse events among other centers.[41] Many complications are potentially life-threatening, and successful treatment of complications depends on prompt action by critical care physicians and/or anesthesiologists cooperating closely with the interventional cardiologists who are manipulating the catheters.

TABLE 32.2

Potential Complications in the Catheterization Laboratory

Procedure	Representative Lesion	Complications

Hemodynamic evaluation	Congenital heart disease Pulmonary hypertension Postoperative course; progress not as expected, persistent low cardiac output state, inability to wean from mechanical ventilation, persistent chylous effusions; evaluate residual intracardiac shunt or outflow tract obstruction	Blood loss requiring transfusion Air embolism Vascular access; trauma, dissection, occlusion, perforation Myocardial perforation and tamponade Arrhythmias; ventricular and supraventricular tachycardia, ventricular fibrillation, complete heart block
Coil embolization	Aortopulmonary collaterals Systemic-pulmonary shunts	Fevers Excessive hypoxemia Systemic embolization
Transcatheter device closure	Patent ductus arteriosus Atrial septal defect Ventricular septal defect Baffle leak	Air or device embolization Blood loss Interference with atrioventricular value function Arrhythmias; ventricular arrhythmias, complete heart block
Balloon and stent dilations	Pulmonary artery stenosis	Pulmonary artery tear and hemorrhage Pulmonary edema: high flow False aneurysm Right ventricle ischemia
	Pulmonary valve stenosis	As above Pulmonary valve regurgitation
	Mitral valve stenosis	Mitral insufficiency Pulmonary hypertension
	Coarctation of the aorta	Aortic dissection Hypertension
	Right ventricular conduit/Percutaneous pulmonary valve	Conduit disruption False aneurysms Stent embolization Pulmonary hemorrhage from distal wire injury
Atrial septostomy	Transposition of the great arteries, mitral stenosis (atresia) with restrictive atrial septum, hybrid procedure	Perforation of the heart and tamponade Atrial arrhythmia Mitral valve injury

Balloon Dilation of Pulmonary Arteries

Pulmonary artery balloon dilation and stent placement to relieve stenosis is a common procedure performed in the catheterization laboratory.[42] Pulmonary artery stenoses may be congenital or acquired lesions. They may be discrete, involving the main or branch pulmonary arteries, or multiple, involving distal segmental vessels. The increase in pulmonary artery pressure and fixed resistance to antegrade pulmonary blood flow may have related and deleterious consequences, which include the following:

1. An increase in the afterload on the RV, which in turn causes right ventricular hypertension. The RV can cope with a significant pressure load for some time. However, as right ventricular end-diastolic pressure increases and tricuspid regurgitation possibly develops, right atrial pressure increases and manifests as hepatomegaly, ascites, and persistent or recurrent pleural effusions.

2. Reduced antegrade flow across the pulmonary outflow, which in turn reduces preload to the left ventricle and contributes to a low cardiac output state. Further, the hypertrophy of the ventricular septum reduces the compliance of the left

ventricle and increases left ventricular end-diastolic pressure.

3. An increase in right ventricular pressure and ventricular hypertrophy may compromise coronary blood flow. Hypotension or tachycardia with altered coronary filling time may cause myocardial ischemia, with the subendocardium being at particular risk.

4. If the pulmonary valve is incompetent, for example, following right ventricular outflow reconstruction for repair of tetralogy of Fallot with or without pulmonary atresia, a considerable amount of pulmonary regurgitation may occur that causes an additional volume load on the RV, leading to right ventricular dilation and systolic failure. In addition, the increased pulsatility to the branch pulmonary arteries may cause extrinsic compression of the main stem bronchi.

Patients with persistent signs of right ventricular failure, such as low cardiac output state, hepatomegaly, ascites, recurrent pleural effusions (particularly if chylous in nature), and inability to wean from mechanical ventilation, should be considered for catheterization. Although echocardiography may help determine a specific problem, catheterization provides quantitative data that can direct vasoactive support and enable interventions such as pulmonary artery dilation, coiling of collateral vessels, and creation of an atrial communication that allows an atrial-level right-to-left shunt.

The function of the right ventricle is critical and often the cause of complications related to pulmonary artery dilation. At the time of balloon dilation, cardiac output may decrease significantly, causing hypotension, bradycardia, arterial oxygen desaturation, and a fall in end-tidal CO_2. Because the balloon is inflated for only a few seconds and provided preload is maintained, the procedure is usually well tolerated and the circulation usually recovers spontaneously. Patients who have a hypertrophied, poorly compliant RV with intraventricular pressures at systemic or suprasystemic levels may not tolerate the sudden increase in afterload associated with balloon dilation, even for a short period. In particular, myocardial ischemia and arrhythmias may occur, causing severe acute right ventricular failure and loss of cardiac output. General anesthesia and controlled ventilation are recommended before intervention in this at-risk group of patients.

Pulmonary artery disruption is signaled by local extravasation of contrast in the lung parenchyma, sudden hemodynamic deterioration from cardiac tamponade or acute hemothorax, or sudden onset of hemoptysis.[43] The tear in the pulmonary artery may be confined (Fig. 32.5A) and therefore controlled, or unconfined, resulting in hemodynamic collapse and the possible need for immediate surgical intervention. The potential for pulmonary artery disruption is increased because of the high pressure used to inflate the balloon and maintain tension on the vessel wall to tear the intima and media. The risk for pulmonary artery disruption may be increased in early postcardiac surgery patients if the dilation is performed across a recent pulmonary artery anastomosis; in the past waiting 6 weeks before dilatation was advocated. However, if there is a continuous suture, and using a stent to avoid recoil, interventions can be safely performed even in the early postoperative period.[33] Thus in the immediate postoperative period, particularly if the patient has severe right ventricular failure, low cardiac output state, or inability to wean from

mechanical ventilation, pulmonary artery dilation should be performed. Cutting balloons have increased options available for achieving successful balloon dilation in resistant lesions with improved efficacy and similar safety profile to high-pressure dilation.[44] A high index of suspicion should be maintained in patients with peripheral pulmonary artery stenosis treated with high-pressure angioplasty or a cutting balloon. In the presence of substantial hemoptysis, immediate endotracheal intubation is indicated for airway control and ventilation. Hypertension and further airway stimulation should be avoided, the addition of positive end-expiratory pressure may be useful, and instillation of 1 mL of 1 : 100,000 epinephrine via the endotracheal tube may help reduce immediate bleeding by causing vasoconstriction of mucosal vessels. An immediate intervention by the catheterizer to tamponade the disrupted branch pulmonary artery with a balloon catheter may be lifesaving. Permanent occlusion of the vessel with a coil (Fig. 32.5B) or covered stent may be necessary to prevent further hemorrhage.

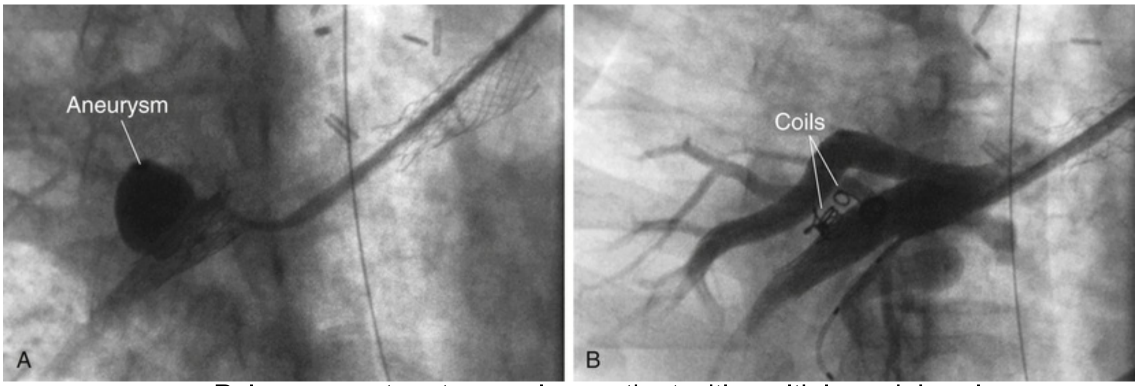

FIG. 32.5 Pulmonary artery trauma in a patient with multiple peripheral pulmonary artery stenoses. (A) Pulmonary artery aneurysm following balloon dilation. Note that a stent has been placed but the aneurysm is still present. (B) Resolution after coils are placed in the neck of the aneurysm.

Transient unilateral or unilobar pulmonary edema is also seen in the setting of pulmonary artery dilation. This finding is related to sudden large increases in pulmonary blood flow and distal pulmonary artery pressure after dilation in a previously underperfused pulmonary vascular bed. Pulmonary edema after dilation usually occurs immediately following balloon dilation but can be delayed for up to 24 hours. Pulmonary edema and disruption of a pulmonary artery can occur abruptly, in isolation, or together, during pulmonary artery dilation procedures. Both can cause the appearance in the airway of frank blood or blood-tinged edema fluid in substantial quantities.

Patients who have a dilated RV secondary to a long-standing volume load, such as chronic pulmonary regurgitation, are at risk for arrhythmias and low output during catheter manipulations and interventions. As noted earlier, on most occasions the changes in rhythm are short-lived and settle once the catheters are withdrawn. Nevertheless, anesthesia and airway control are recommended if the circulation is compromised, and a defibrillator and transvenous pacing must be immediately available.

Potential movement at the time of critical balloon dilation or stent placement must

be prevented. Dilation of pulmonary arteries is painful and often causes patients to waken from sedation and move. In addition, dilation of the pulmonary arteries may induce coughing. The coughing is usually not a problem for isolated pulmonary artery dilation, but if the patient moves during stent placement, stent malposition or embolization can occur. Therefore the patient must be immobile, and additional sedation should be considered immediately before stent placement.

Occlusion Device Insertion

Although device closures of PDA and ASD are commonly performed interventions in the catheterization laboratory, they are relatively uncommon procedures in pediatric intensive care patients. A persistent left-to-right shunt at the atrial level contributing to right ventricular volume overload, increased pulmonary blood flow, and inability to wean from mechanical ventilation may be one indication for occlusion, although often the ASD must be of considerable size to cause these symptoms and may be too large for safe deployment of the device. Conversely, a large right-to-left shunt across an ASD may result in significant cyanosis and increase the risk for paradoxical embolism and cerebral vascular accident. A similar circumstance exists in patients who have undergone a fenestrated Fontan operation. Placement of a PDA[45] or ASD[46] device is usually associated with minimal hemodynamic disturbance. Although placement can be performed in most patients using sedation techniques, endotracheal tube placement for airway protection may be necessary if transesophageal echocardiography is used to guide device placement.

Indications for VSD device placement include closure of a residual or recurrent septal defect, preoperative closure of defects that may be difficult to reach surgically while on CPB, and closure of acquired defects such as those due to myocardial infarction or trauma. A residual VSD may cause considerable volume load to the ventricles and result in a low cardiac output state and congestive heart failure requiring prolonged mechanical ventilation and inotropic or vasoactive support. In contrast to closure of PDAs or ASDs, transcatheter VSD device closures are prolonged procedures that are often associated with profound hemodynamic instability and blood loss.[47] Although the technique has not changed over time, the devices available now have much smaller delivery systems that result in reduced sheath size and less hemodynamic compromise (Fig. 32.6).[48] However, all patients should be considered susceptible. Factors contributing to hemodynamic instability include blood loss, arrhythmias from catheter manipulation in the ventricles and across the septum, heart block from trauma to conduction system, atrioventricular or aortic valve regurgitation from stenting open of valve leaflets by stiff wire/catheters, and device-related factors such as malposition or dislodgment from the ventricular septum.

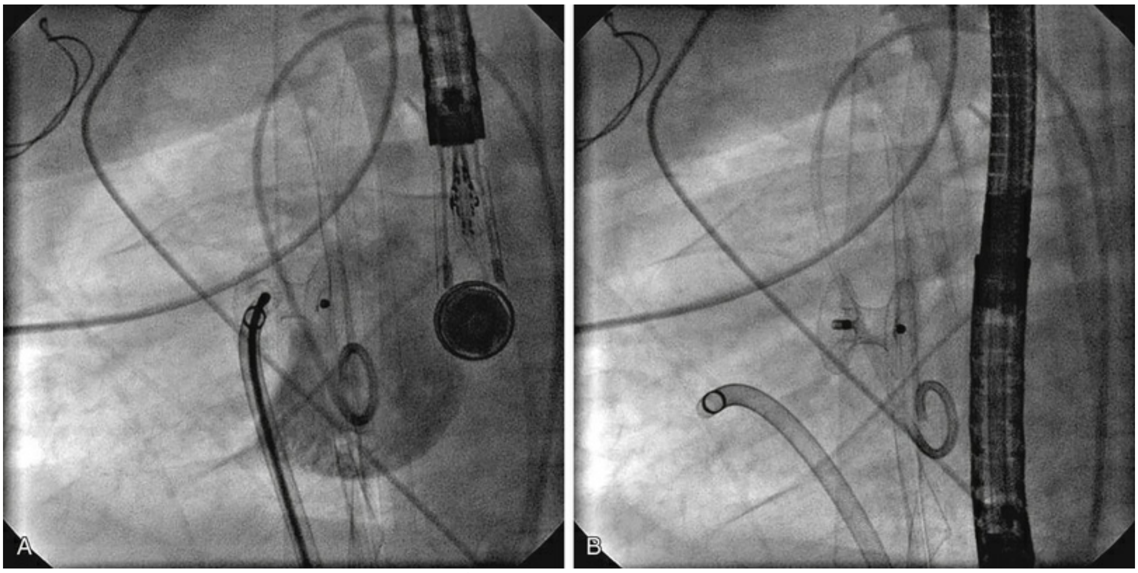

FIG. 32.6 Ventricular septal defect closure using the Amplatzer muscular VSD device. (A) Left ventricular angiogram during device delivery from the venous side. (B) Device after release. The pigtail catheter is in the left ventricle. The long sheath that delivered the device is in the right ventricle.

In all device closures, the long delivery sheath represents a potential space for air accumulation and risk for air embolism. In patients with intracardiac shunts, air embolization may be life-threatening and can be diagnosed by fluoroscopy. Extreme inspiratory efforts may introduce air into the sheath and the heart. Air in the right atrium may be shunted across an ASD even in the presence of nominal left-to-right shunting. Left heart air embolization produces ST-segment elevation and, often, hemodynamic changes as it passes into the aorta. The resultant ST-segment changes, hypotension, arterial desaturation, and bradycardia generally respond to aspiration and then sealing of the entry port, along with administration of atropine and inotropic and pressor support to maintain coronary perfusion. Meticulous purging of air from the catheter system and sealing of open ports help minimize the incidence of air embolism. Use of positive pressure ventilation through an endotracheal tube in an anesthetized, paralyzed patient also may decrease the potential for transcatheter air embolus.

Cardiac Catheterization and Extracorporeal Membrane Oxygenation

Cardiac catheterization may be necessary in patients supported with ECMO for either diagnostic or therapeutic procedures, often to facilitate subsequent weaning and decannulation.[49] Reversible respiratory failure and pulmonary hypertension remain common indications for ECMO, but mechanical support of the failing circulation using ECMO has been increasingly used. Indications include refractory low cardiac output state, unexpected cardiac arrest, failure to wean from CPB, severe cyanosis, and refractory arrhythmias.[13,50] ECMO has also been used as a highly successful tool in the resuscitation of patients following hemodynamic deterioration due to catheter-induced complications, low output, or hypoxemia.[51]

A number of published series have described the feasibility and utility of cardiac catheterization of patients supported by ECMO.[52-54] Indications for catheterization have included assessment of surgical repair and interventions to treat residual defects, left heart decompression via a percutaneous transatrial vent in order to prevent overdistension of the left ventricle, hemodynamic assessment and myocardial biopsy in patients with fulminant myocarditis/cardiomyopathy, and catheter-based interventions such as arrhythmia ablation.

As already discussed in patients not following an expected clinical course, it is important to have a high index of suspicion for residual lesions in postoperative cardiac surgery patients who cannot be weaned from ECMO within 72 hours of expected myocardial recovery. Early catheterization and subsequent interventions may facilitate recovery of myocardial function, reduce ECMO duration, and lessen the potential for ECMO-related complications.

The use of percutaneously inserted mechanical circulatory support is a rapidly expanding field in adult cardiology,[55] and some of these technologies are applicable to pediatric patients.[56] An awareness of newer percutaneous means for providing short-term hemodynamic support is important for critical care physicians to be aware of, as well as an area likely to rapidly evolve.

CHAPTER 33

Pharmacology of the Cardiovascular System

Naomi B. Bishop, Bruce M. Greenwald, Daniel A. Notterman

PEARLS

- Clinical acumen is necessary to distinguish between the need for an inotropic agent, which is used to increase cardiac contractility, and the need for a vasopressor agent, which is used to increase vascular tone.
- The failing myocardium may need to be supported with an agent that increases contractility and reduces afterload, such as milrinone or dobutamine.
- Multiple polymorphisms have been discovered in receptors relevant to the intensivist. Although the clinical importance of these polymorphisms has yet to be determined, physicians need to stay abreast of changes in this rapidly expanding area.

In many pediatric critical care units, disorders of the cardiovascular and respiratory systems are the most frequent reasons for admission. Children with these disorders constitute a large group who may require pharmacologic support to maintain adequate end-organ perfusion and oxygenation. The catecholamines are the class of drug most often used for this support, and they remain a mainstay of therapy for the pediatric critical care physician, although the role of other agents has expanded. Milrinone, a bipyridine, has been used to support patients with hemodynamic compromise of varying etiologies. In addition, the role of vasopressin and terlipressin in the management of patients with vasodilatory shock or after cardiopulmonary bypass continues to grow. This chapter examines the clinical pharmacology of the five clinically useful catecholamines, as well as newer agents and the venerable cardiac glycosides.

Mechanisms of Response

Pharmacologic manipulation of the cardiovascular system often entails increasing the inotropic state of the myocardium or altering the tone of the systemic vascular

tree so as to improve perfusion. The final common mediator for both processes is the concentration of calcium in the cytosol. The pathway by which pharmacologic agents affect this parameter is a function of their specific cell surface receptors.

Adrenergic Receptors

Catecholamines modify cellular physiology through their interaction with specific adrenergic receptors. The classic paradigm of α and β classes of adrenergic receptors remains unchanged, although new subtypes and sub-subtypes continue to be identified. Currently three subtypes of α_1 receptors (A, B, D), three subtypes of α_2 receptors (A, B, C), and three subtypes of β receptors (β_1, β_2, β_3) are recognized.[1] Advances in the biology of the adrenergic receptor have led to a greater understanding of role of the α receptor in the heart, adrenergic receptor regulation of cardiac myocyte apoptosis, and the coupling of the β_2 receptor to more than one G protein. The discovery of various genetic polymorphisms for the adrenergic receptors has added even more complexity, but the clinical relevance of many of these polymorphisms and their role in the pathogenesis of disease are only beginning to be elucidated. Despite this increase in our understanding of the adrenergic receptor, the clinical classification of the catecholamines into α and β agents remains functionally unchanged (Table 33.1).

TABLE 33.1

Adrenergic Receptors: Physiologic Responses, Agonist Potency, and Representative Antagonists

Receptor	G Protein	Physiologic Response	Agonist	Antagonist
α_1	G_q	Increase $InsP_3$, 1,2-DG, and intracellular Ca^{+2}; muscle contraction; vasoconstriction; inhibit insulin secretion	E > NE > D	Prazosin
α_2	G_i	Decrease cAMP; inhibit NE release; vasodilation; negative chronotropy	E > NE	Yohimbine
β_1	G_s	Increase cAMP; inotropy, chronotropy; enhance renin secretion	I > E ≥ D ≥ NE	Propranolol, metoprolol
β_2	G_s	Increase cAMP; smooth muscle relaxation; vasodilation; bronchodilation; enhance glucagon secretion; hypokalemia	I ≥ E > D > NE	Propranolol
D_1	G_s	Increase cAMP; smooth muscle relaxation	D	Haloperidol, metoclopramide
D_2	G_i	Decrease cAMP; inhibit prolactin and β-endorphin	D	Domperidone

cAMP, cyclic adenosine monophosphate; *D*, dopamine; *1,2-DG*, 1,2 diacylglycerol; *E*, epinephrine; *I*, isoproterenol; *InsP3*, Inositol 1,4,5-triphosphate; *NE*, norepinephrine.

Modified from Notterman DA. Pharmacologic support of the failing circulation: an approach for infants and children. Prob Anesth. 1989;3:288.

Signal Transduction

Adrenergic receptors mediate their effects through G proteins and as such are classified as G protein–coupled receptors. The adrenergic receptor itself contains seven membrane-spanning α-helical domains, an extracellular N-terminal segment, and a cytosolic C-terminal segment (Fig. 33.1). G proteins are heterotrimeric proteins consisting of α, β, and γ subunits, each of which has multiple subfamilies.[2] There are at least twenty α subunits, five β subunits, and six γ subunits. The action mediated by a ligand binding to a particular adrenergic receptor is a function of the specific

subunits comprising the G protein receptor complex.

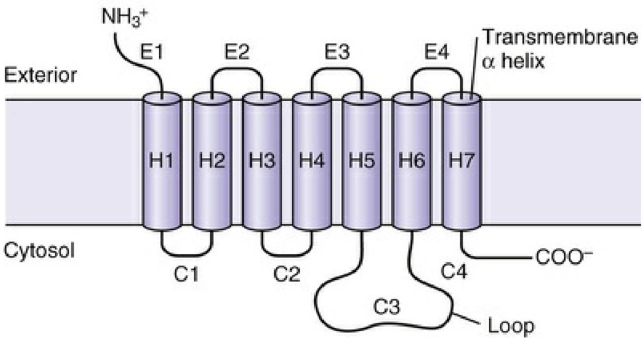

FIG. 33.1 Schematic representation of typical G protein–coupled receptor with seven membrane spanning regions (H1–H7), cytoplasmic (C1–C4), and extracellular (E1–E4) loops. (From Lodish H, et al. Molecular Cell Biology. 4th ed. New York, NY: WH Freeman; 1999.)

Adrenergic receptors typically are coupled to one of three types of G proteins: G_s, G_i, or G_q. G_s proteins produce an increase in adenylate cyclase activity, while G_i proteins inhibit adenylate cyclase activity. G_q protein receptors stimulate phospholipase C to generate diacylglycerol and inositol 1,4,5-triphosphate. The nature of the G protein is usually a function of the type of α subunit (α_s, α_I, α_q, and $\alpha_{12/13}$).[2-4] Events involving interaction of G proteins, the receptor protein, and adenylate cyclase are summarized in Fig. 33.2. In the example of the G_s protein, ligand binding to the coupled receptor causes a conformational change in the G protein, resulting in guanosine diphosphate (GDP) disassociating from the Gsα subunit and guanosine triphosphate (GTP) binding to the α subunit. This GTP-Gα complex then disassociates from the G$\beta\gamma$ subunit and binds to adenylate cyclase, leading to an increase in activity of this enzyme. Adenylate cyclase catalyzes the conversion of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP), thus increasing cellular levels of cAMP. G_i proteins have a different α subunit; when the $G_i\alpha$ GTP complex binds to adenylate cyclase, the enzyme is inactivated. By inhibiting this enzyme, G_i-coupled receptor agonists produce a decrease in the cellular concentration of cAMP. The specific cellular response that follows an alteration in the concentration of cAMP depends on the specialized function of the target cell.[2] Typically, an increase in concentration of cAMP leads to activation of a cAMP-dependent protein kinase. These kinases then phosphorylate and activate other structures and enzymes. Many compounds other than adrenergic agents also increase intracellular levels of cAMP. The question of how various agents produce specific responses through the expression of common second messengers continues to be investigated. One proposed mechanism involves anchoring proteins, such as A kinase anchoring proteins. These proteins localize protein kinase A (PKA) to particular cellular locales and also may offer binding sites for other regulatory proteins.[4] Similarly, anchoring proteins for both the active and inactive forms of protein kinase C have been described.[5] Different subtypes of anchoring proteins may serve to create another level of specificity in the effector response for a particular ligand by confining the response to a particular area of the cell.

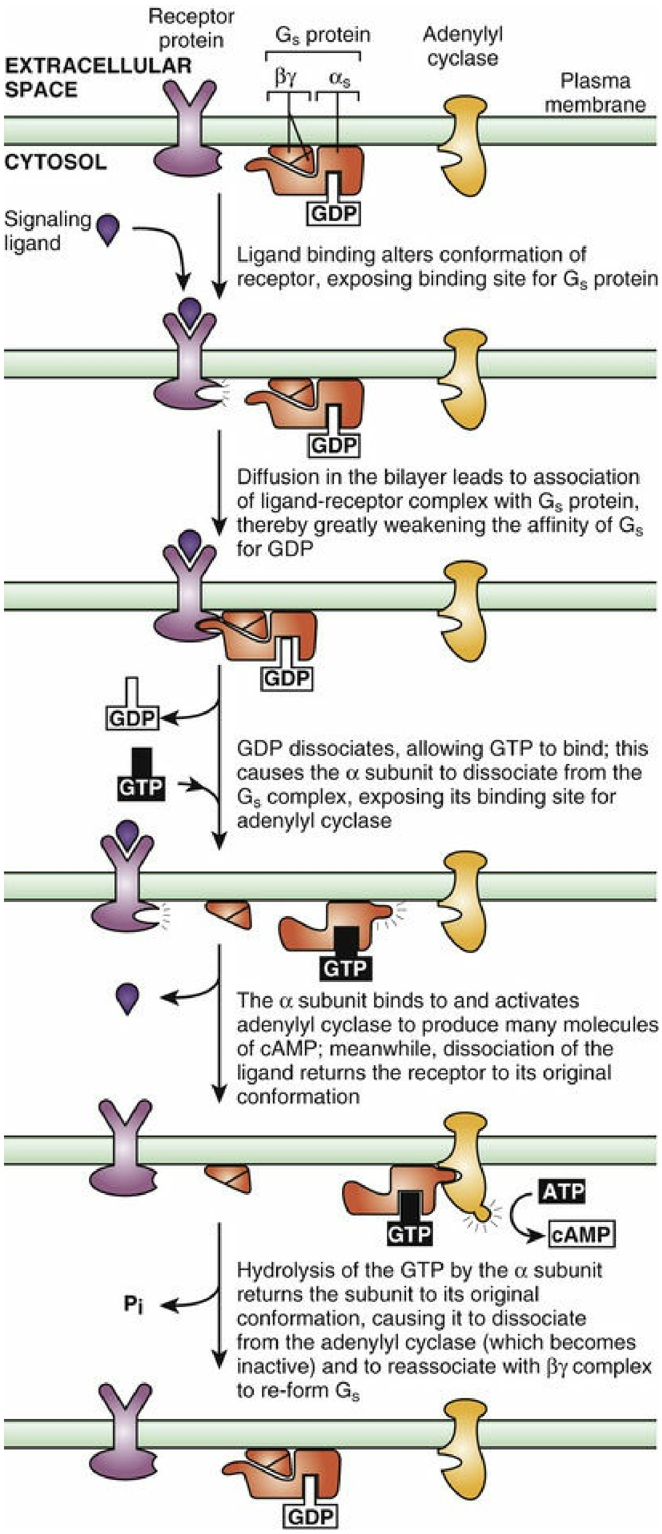

FIG. 33.2 Adrenergic receptor complex. When the receptor is engaged by an appropriate ligand (eg, isoproterenol for a β_1 receptor), the receptor associates with the α_s polypeptide of the G_s protein. This causes the α_s to extrude GDP and incorporate GTP; α_s then associates with and activates the adenylate cyclase. The process is terminated when GTP is hydrolyzed to GDP and α_s dissociates. (From Alberts B, et al. Molecular Biology of the Cell. 3rd ed. New York, NY: Garland Science; 1994. Reproduced by permission of Garland Science/Taylor Francis, LLC.)

β-Adrenergic Receptors

Myocardial β_1-adrenergic receptors are associated with G_s. When this receptor type is engaged by an agonist agent, the result is enhanced activity of adenylate cyclase and a rise in the concentration of cAMP. This process activates PKA. PKA in turn phosphorylates voltage-dependent calcium channels, increasing the fraction of channels that can be opened and the probability that these channels are open, producing an increase in intracellular calcium concentration (Fig. 33.3).[6] Calcium then binds to troponin C, allowing for actin-myosin cross-bridge formation and sarcomere contraction. In addition, PKA phosphorylates phospholamban, relieving the disinhibitory effect of the unphosphorylated form on calcium channels in the sarcoplasmic reticulum. The accumulation of calcium by the sarcoplasmic reticulum is thus enhanced, increasing the rate of sarcomere relaxation (lusitropy) and subsequently increasing the amount of calcium available for the next contraction. This process leads to both enhanced contractility and active diastolic relaxation.

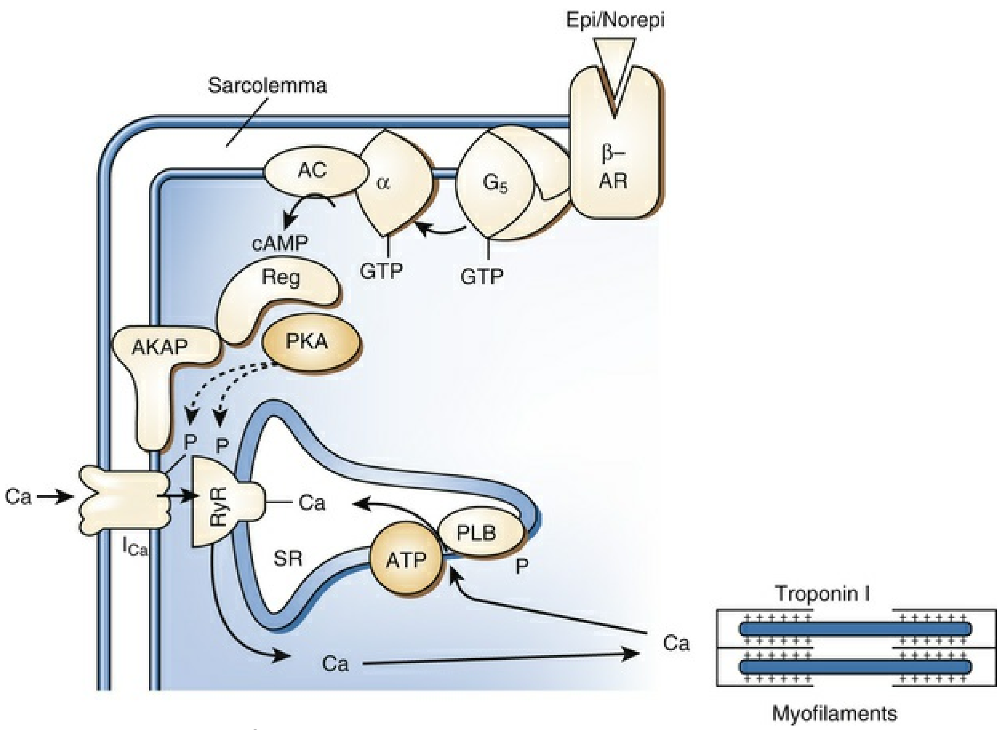

FIG. 33.3 β_1-Adrenergic receptor signaling cascade. Agonist (epinephrine/norepinephrine [Epi/Norepi]) to β-adrenergic receptor (β-AR) results in the α subunit binding to GTP, which activates adenylate cyclase (AC). AC then converts adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP), which binds to regulatory unit (Reg) on protein kinase A (PKA). PKA then promotes an increase in the intracellular concentration of calcium (Ca) by acting on voltage-gated channels (I_{Ca}) and on the sarcoplasmic reticulum (SR). Cardiac excitation-contact coupling then promotes sarcomere contraction. *AKAP,* A kinase anchoring protein; *PLB,* phospholamban; *RyR,* ryanodine receptor. (From Bers DM. Cardiac excitation-contact coupling. Nature. 2003;415:198.)

Both β_1 and β_2 receptors are present in vascular smooth muscle, although β_2

receptors predominate.[1] The β_2 receptor is coupled to G_s; therefore activation of β_2 receptors promotes formation of cAMP. The activation of cAMP-dependent protein kinase in vascular smooth muscle, however, stimulates pumps that remove calcium from the cytosol and also promotes calcium uptake by the sarcoplasmic reticulum. As cytosolic calcium concentration decreases, smooth muscle relaxes and the blood vessel dilates.

α Receptors

Vascular smooth muscle contraction is mediated via α_1-adrenergic receptors, of which there are three subtypes: 1A, 1B, and 1D. The individual contributions of each of these subtypes to the control of vascular tone is an active area of investigation. Each subtype may be expressed in all of the vascular beds, but it is thought that one type predominates in any particular bed.[7] A mouse knockout model of the α_{1D} receptor showed that α_1 binding in the aorta was lost but preserved in the heart. The knockout model also had lower blood pressures and a decreased response to norepinephrine.[8] α_{1A} and α_{1B} receptors are thought to be involved in both the heart and vasculature.[9,10] A knockout model of α_{1A} demonstrated both decreased blood pressure and a decreased response to phenylephrine.[7] An animal model of overexpression of the α_{1A} receptor was associated with marked increase in cardiac contractility without a change in blood pressure or heart rate.[11] In a knockout model of α_{1B} receptors in mice, chronic exposure to norepinephrine did not lead to cardiac hypertrophy or vascular remodeling.[12] Overexpression of a mutant α_{1B} receptor led to increased expression of mitogen-activated protein kinases and decreased responsiveness to isoproterenol in isolated cardiac preparations.[13] Thus while α receptors may have less inotropic effect than β-adrenergic receptors, they do have significant effects in the myocardium. Interestingly, in patients with heart failure, downregulation of β receptors has been noted while α receptors are preserved.[14] In fact, recent evidence suggests that α_1 receptors may display cardioprotective effects including activation of adaptive hypertrophy, increased contractility, and prevention of myocyte death.[15] The α_1 receptor is coupled to the family of $G_{q/11}$ proteins, which act independently of cAMP. Signal transduction across this receptor is initiated by the activation of phospholipase C, which hydrolyzes phosphatidylinositol 4,5-biphosphate to inositol 1,4,5-triphosphate ($InsP_3$) and 1,2-diacylglycerol (1,2-DG). $InsP_3$ binds to specific receptors on the sarcoplasmic reticulum, causing a release of calcium into the cytosol, and promotes movement of extracellular calcium into the cell. 1,2-DG with calcium activates protein kinase C (PKC), which regulates movement of calcium into the cytosol (Fig. 33.4). In vascular smooth muscle, medium light chain kinase is activated as a result and phosphorylates myosin light chain 2, leading to smooth muscle contraction.[16] A similar mechanism underlies the inotropic effect of the α_1 receptor in the myocardium.[17] The α_{1A} receptor appears to be the most efficiently coupled of the different subtypes.[18] The α_1 receptors also activate calcium influx through voltage-dependent and voltage-independent calcium channels.[19] The α receptors also promote the activation of the mitogen-activated kinase family, which are key regulators of cell growth.

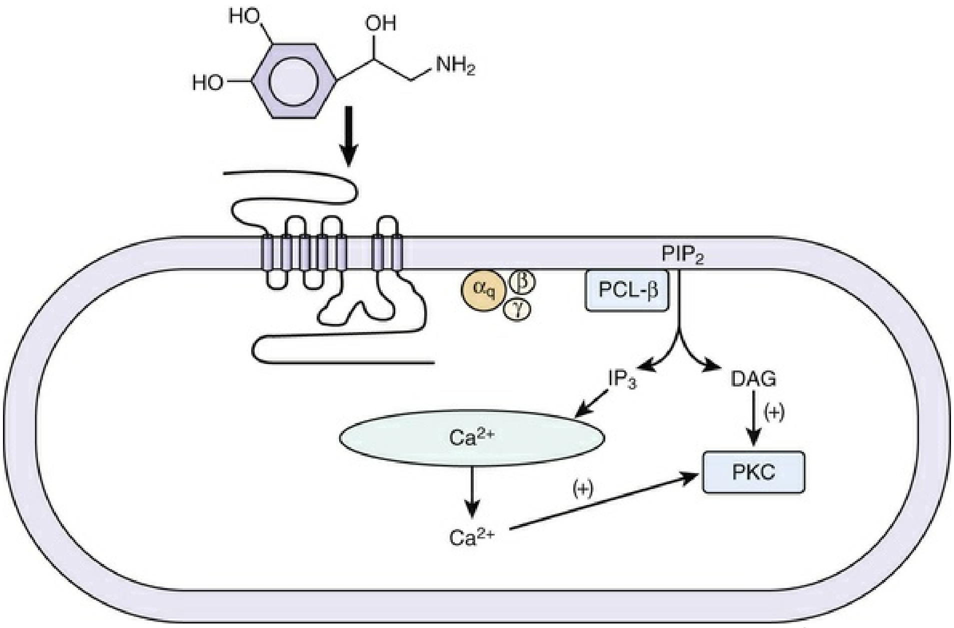

FIG. 33.4 α_1-Adrenergic receptor signaling cascade. Binding of an agonist such as norepinephrine to a G protein–coupled receptor activates the $G_{q/11}$ protein, leading to disassociation of the α and βγ subunits. Phospholipase C (PLC-β) is activated in turn and cleaves phosphatidylinositol 4,5-biphospate (PIP_2) to inositol 1,4,5-triphosphate (IP_3) and diacylglycerol (DAG). IP_3 and DAG promote an increase in intracellular calcium through the sarcoplasmic reticulum and protein kinase C (PKC). (From Zhong H, Minneman KP. α-1 adrenoreceptor subtypes. Eur J Pharm. 1999;375:26.)

Receptor Downregulation

The mechanisms described provide numerous sites at which activity of the system can be modified, thereby affecting the sensitivity of target cells to both exogenous and endogenous catecholamines. Some of these receptor modifications are clinically important to the critical care physician. The best-documented type of modification involves agonist-mediated receptor desensitization. Exposure of receptors to agonists markedly reduces the sensitivity of the target cell to the agonist. Within seconds to minutes after agonist binding, the receptor may be uncoupled as a result of receptor phosphorylation. The receptor may be phosphorylated by PKA or PKC or by a member of the family of G receptor kinases (GRKSs). These kinases, which include β-adrenergic receptor kinases 1 and 2, phosphorylate only receptors that have agonist bound. Compared with PKA and PKC, phosphorylation by GRKS enhances the ability of β arrestin, a cytosolic protein, or clathrin to bind to the receptor and disrupt further signaling. The role of GRKS has been established for β_1, β_2, and α_2 receptors.[20,21] Sequestration of receptors within the target cell and degradation of sequestered receptors are other mechanisms by which receptors are downregulated. The desensitization of α_1 receptors has been extensively reviewed.[22] Homologous desensitization is mediated by GRKSs, which are activated by soluble $G\beta\gamma$ subunits and phosphatidylinositol biphosphate. As with the other adrenergic receptors, once phosphorylated, the receptors are internalized into vesicles. The α_1 receptors also demonstrate heterologous desensitization, in which a second

messenger kinase, generated as a result of ligand binding, inactivates the receptor and prevents any further signaling. In addition to agonist-mediated desensitization, other stimuli also have been implicated in downregulation, including endotoxin, tumor necrosis factor, and congestive heart failure (CHF).[23] Lymphocyte β-adrenergic receptor density in children with CHF was reduced in proportion to the degree of elevation in plasma norepinephrine concentration.[24]

Polymorphisms

Several types of genetic polymorphism have been detected within the genes that code for signaling cascades that are involved in adrenergic signaling. These variants include single nucleotide polymorphisms (SNPs), copy number variants (CNVs), and variable number tandem repeats (VNTRs). Growing literature suggests that some of these polymorphisms may be implicated in interindividual differences in severity, periodicity, or response to treatment of asthma.[25]

Whereas several variants in genes encoding cytokines and other mediators of inflammation have been associated with severity or outcome of septic shock, there are few well-documented examples of functional genetic variants in adrenergic signaling that affect critical illness in children. In one study of adults with septic shock, an SNP in the β_2 receptor was associated with greater organ dysfunction and mortality.[26] Other polymorphisms have been associated with the β_1 receptor. Although these variants affect some properties of receptor function, clinical links are still being explored.[27-29] Recently, the Arg 389 β_1 variant has been shown to moderate the effect of β blockers on various cardiovascular measures, suggesting that it may become appropriate to test for this variant when considering therapy with an agent of this class. Interestingly, the Arg 389 β_1 variant has also been associated with increased cAMP generation, poorer prognosis in heart failure, and an increase in the predisposition to hypertension.[30]

Vasopressin Receptors

Arginine vasopressin is a nonpeptide hormone synthesized in the supraoptic and paraventricular nuclei of the hypothalamus. Three subtypes of vasopressin receptors exist, known as V_1, V_2, and V_3 (or V_{1b}). V_2 receptors are present in the renal collecting duct, while V_1 receptors are located in vascular beds, kidney, bladder, spleen, and hepatocytes, among other tissues.[31] Vasopressin is released in response to small increases in plasma osmolality or large decreases in blood pressure or blood volume.[32] The plasma osmolality threshold for release of AVP is 280 mOsm/kg; above this threshold there is a steep linear relation between serum osmolality and vasopressin levels.[32] Changes in blood volume of at least 20% in blood volume are necessary to effect a change in vasopressin levels, although levels may then increase by 20- to 30-fold.[32] Hypovolemia also shifts the vasopressin response curve to osmolar changes to the left and increases the slope of the curve (Fig. 33.5). Vasopressin can produce vasoconstriction through V_1 receptors in the vascular bed (discussed later), but it also activates V_1 receptors in the central nervous system (CNS), including receptors in the area postrema.[33] This region is responsible for the reflex bradycardia seen with vasopressin infusion, which attenuates the increase in

blood pressure that would result from the vasoconstrictor effects of vasopressin.[34,35] In fact, vasopressin causes a greater reduction in heart rate than other vasoconstrictors.[31] Thus if this feedback loop is abolished, vasopressin induces a greater vasopressor response than other agents.[33]

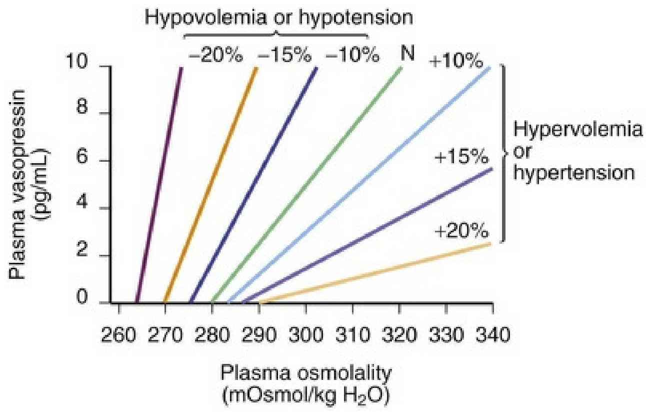

FIG. 33.5 Relationship between plasma vasopressin levels and plasma osmolality. As hypovolemia worsens, vasopressin levels increase for any given plasma osmolality. (Modified from Robertson GL, Athar S, Shelton RL. Osmotic control of vasopressin function. In: Androli TE, Grantham JJ, Rector FC Jr, eds. Disturbances in body fluid osmolality. Bethesda, MD: American Physiological Society; 1977.)

V_1 Receptors

Vasopressin receptors belong to the family of G protein–coupled receptors. V_1 receptors are coupled to G_q, and V_2 receptors are coupled to G_s.[32] When vasopressin binds to the V_1 receptor, phospholipase C is activated with the eventual production of $InsP_3$ and 1,2-DG. These molecules serve to increase the release of calcium from the endoplasmic reticulum, as well as increase the entry of calcium through gated channels (Fig. 33.6).[36] The increase in intracellular calcium leads to an increase in the activity of myosin light chain kinase. This kinase acts upon myosin to increase the number of actin-myosin cross-bridges, enhancing contraction of the myocyte. Of note, vasopressin has been shown to produce vasoconstriction in the skin, skeletal muscle, and fat while producing vasodilatation in the renal, pulmonary, and cerebral vasculature.[37] This effect may be mediated though nitric oxide or may be a function of the isoform of adenyl cyclase with which the receptor is coupled.[38] Vasopressin has also been shown to augment the pressor effects of catecholamines, although in two different vascular smooth muscle cell lines, vasopressin had opposing effects on isoproterenol-induced activation of adenyl cyclase.[39-41] Other effects of vasopressin binding to V_1 receptors are shown in Fig. 33.6.

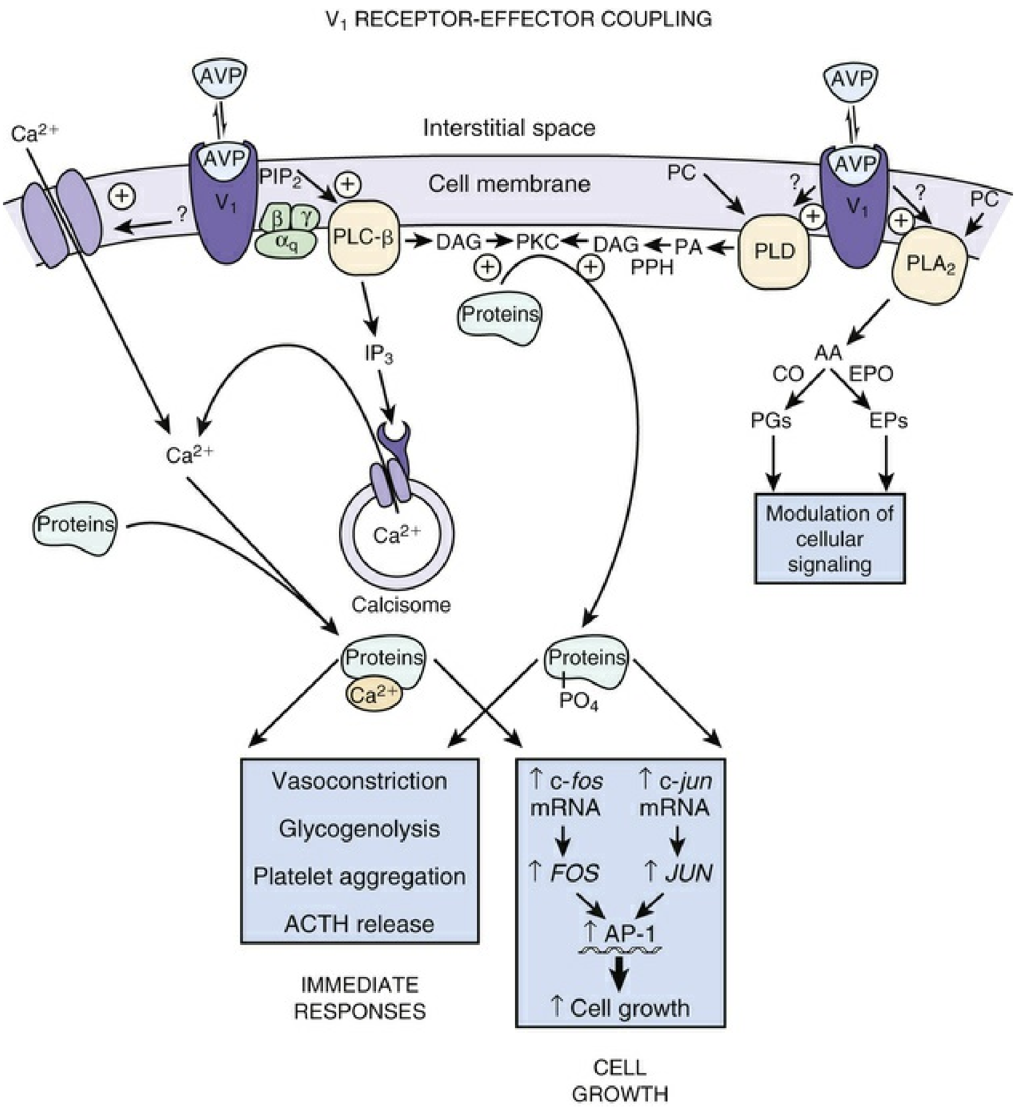

FIG. 33.6 V_1 receptor signaling cascade. Binding of arginine vasopressin (AVP) to the V_1 vasopressin receptor (V_1) leads to activation of phospholipase C (PLC-β) via the Gq protein with the production of inositol 1,4,5-triphosphate (IP_3). IP_3 promotes an increase in intracellular calcium, resulting in figure. *AA,* arachidonic acid; *ACTH,* adrenocorticotropic hormone; *AP-1,* transcription factor consisting of heterodimer of FOS and JUN; *CO,* cyclooxygenase; *DAG,* diacylglycerol; *EPO,* epoxygense; *EPs,* epoxyeicosatrienoic acids; *PA,* phosphatidic acid; *PC,* phosphatidylcholine; *PGs,* prostaglandins; *PIP_2,* phosphatidylinositol 4,5-biphosphate; *PKC,* protein kinase C; *PLA_2,* phospholipase A_2; *PLD,* phospholipase D; *PPH,* phosphatidate phosphohydrolase. "?" indicates the mechanism of coupling is unclear. (From Jackson EK. Vasopressin and other agents affecting the renal conservation of water. In: Hardman JG, Limbird LE, eds. Goodman and Gilman's the Pharmacologic Basis of Therapeutics. 10th ed. New York, NY: McGraw Hill; 2001.)

Vasopressin may also increase vascular tone by interacting with so-called ATP-sensitive potassium channels termed K_{ATP}.[42] Activation of K_{ATP} channels hyperpolarizes the cell, closes calcium channels, and prevents contraction.[43,44] The result may be to protect the cell.[27] Vasopressin can induce PKC, which in turn inhibits the K_{ATP} channel when the cellular concentration of ATP is low,[28] allowing

for cell depolarization and calcium entry, resulting in vasoconstriction (Fig. 33.7).[45] V_1 receptors have been demonstrated to have a weakly positive inotropic effect in the heart, although the clinical significance of this effect has not been established.[29]

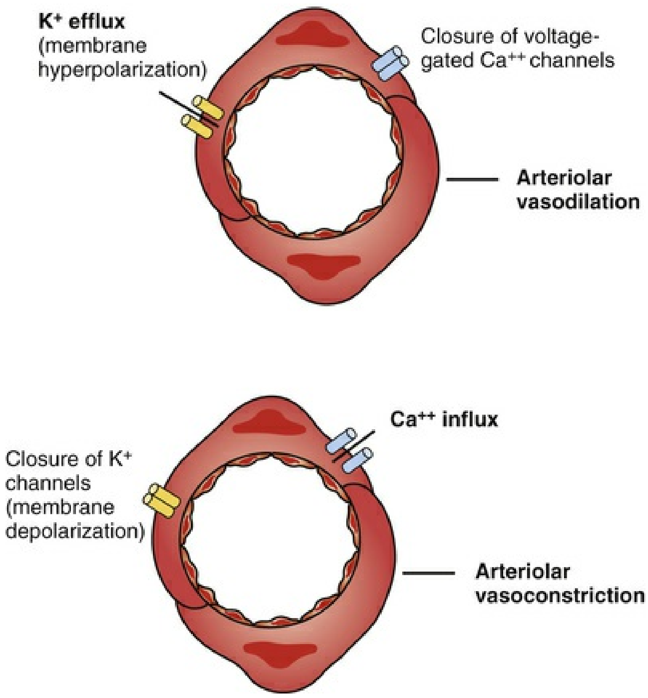

FIG. 33.7 K^+ channels and vascular tone. Diffusion of K^+ through open K_{ATP} channels in vascular smooth muscle cell results in membrane hyperpolarization, closure of voltage-gated Ca^{2+} channels, and decreased intracellular calcium, resulting in vasodilation. Closing of K_{ATP} channels has the opposite effects. (From Jackson W. Ion channels and vascular tone. Hypertension. 2000;35:173-178.)

Receptor Downregulation

As with adrenergic receptors, vasopressin receptors undergo downregulation. Vasopressin promotes the phosphorylation of it own receptor immediately after binding. The receptor is removed from the cell surface within 3 minutes after binding.[46] As with adrenergic receptors, GRKSs catalyze the phosphorylation of the receptor. PKC also mediates this reaction and may serve as the means by which other agents downregulate the vasopressin receptor in a heterologous manner.[46]

Polymorphisms

Although numerous mutations in the V_2 receptor exist, some of which result in nephrogenic diabetes insipidus, much less is known about the V_1 receptor. One study established two polymorphisms in the V_1 receptor gene but failed to establish a linkage with hypertension.[47]Another study involving 33 subjects, designed to evaluate a possible linkage to differences in platelet aggregation in response to vasopressin, identified four single nucleotide polymorphisms in the promoter region of the V1a receptor.[48] No difference in response was observed in subjects with and

without the variant alleles. Still, the molecular basis for individual genetic variation remains an active area of investigation since discoveries in this area may inform risk stratification, prognostic accuracy, and individual response to therapy.

Phosphodiesterase Regulation of cAMP

Phosphodiesterases are a class of enzyme that catalyzes the hydrolysis of cAMP and cGMP into AMP and GMP, respectively. Therefore these enzymes can downregulate the signals transduced by cAMP, such as PKA activity (discussed previously). Several families of this enzyme exist, each with subtypes. Phosphodiesterase III (PDE3) is present in many cell types, including cardiac myocytes, vascular smooth muscle cells, adipocytes, platelets, and pancreatic islet cells. PDE3 has a much higher Vmax (ie, rate of reaction when the enzyme is saturated with substrate) for cAMP than it does for cGMP and therefore is functionally a cAMP esterase.[49] Different isoforms of PDE3 are present in cardiac (PDE3A1) and vascular smooth muscle cells (PDE3A2) and are localized to different cellular compartments. Thus they are able to regulate the function of their target enzymes in response to specific cellular signals.[50] The C-terminus of the enzyme codes for the central catalytic core that is the active binding site, and the N-terminus coding region (may) determine cellular targeting.[51] The bipyridines, such as milrinone, are competitive inhibitors of PDE3; that is, they bind to PDE3, preventing the enzyme from binding to cAMP.[52,53] They appear to bind near the binding site for cAMP, although different PDE3 inhibitors may have different binding sites.[54] Inhibition of PDE3 produces an increase in cAMP, resulting in a positive inotropic effect in the myocardium and vasodilatation in the systemic and pulmonary vasculature.[55] In contrast, methylxanthines such as theophylline, which inhibit all phosphodiesterases, cause levels of both cGMP (thought to decrease contractility) and cAMP to increase. This dual increase attenuates the overall inotropic effect. Bipyridines may also enhance contractility by increasing the sensitivity of myofilaments to cytosolic calcium.[56] Milrinone has been shown to enhance the sarcomere uptake of calcium and thereby augment left ventricular (LV) relaxation (lusitropy).[57] In the peripheral vasculature, PD3 inhibitors produce vasodilatation via a cGMP mechanism.[58] The clinical effect of bipyridine administration is a combination of positive inotropy, lusitropy, and afterload reduction. It has been speculated that long-term exposure to PDE inhibitors may result in adrenergic receptor desensitization via heterologous desensitization, although this has not been demonstrated clinically.[59]

ATPase Inhibition

Membrane-bound sodium-potassium adenosine triphosphatase (Na-K ATPase) is responsible for maintaining electrochemical gradients across the cellular membrane. It does so by extruding three molecules of sodium from the cell and incorporating two molecules of potassium into the cell, both against their respective concentration gradients. This process occurs at the cost of one molecule of ATP. The enzyme consists of an α and β subunit; there are four subtypes of α and three of β.[60] The β subunit may be involved in the trafficking of the enzyme.[61] The α subunit contains both the binding site and catalytic site.[60] The isoforms expressed are dependent on the type of tissue.[62] Cardiac glycosides (eg, digoxin) inhibit the Na-K ATPase pump,

thereby increasing intracellular sodium. The elevation in intracellular sodium alters the transmembrane gradient, thus inhibiting the activity of the voltage-gated sodium/calcium exchange (NCX) pump. This pump exchanges three molecules of extracellular sodium for one molecule of intracellular calcium.[63,64] The net result is a rise in intracellular calcium and, in the cardiac myocyte, enhanced contractility. No evidence exists to suggest the development of tolerance to digoxin with long-term use.[65]

Developmental Issues

It is often stated that the immature myocardium is less sensitive to inotropic agents than the adult heart. The exact nature of the mechanism responsible for these differences represents an area of active investigation. The majority of studies involve animal models or isolated human tissue. Because there are inherent differences between intact healthy animal models and the ill child, as well as pharmacokinetic differences between the infant and adult patient, caution must be exercised when extrapolating laboratory data to the bedside.[66] Nonetheless, a brief review of developmental differences is appropriate.

Age-related differences exist in the response of the developing myocardium to inotropic agents, receptor regulation, and calcium handling. However, the extent of these differences depends on the species studied and the model of illness to which the animals are exposed.[67-72]

Developmental differences also may exist in the expression of phosphodiesterase (PDE) isoforms. In a model of rabbit ventricular myocytes, administration of IBMX (a nonselective PDE inhibitor) and rolipram (a PDE type IV inhibitor) increased intracellular calcium currents in neonatal cells both at baseline and in response to isoproterenol but not in adult cells. In contrast, milrinone (a PDE type III inhibitor) increased intracellular calcium currents at baseline and in response to isoproterenol only in the adult cells.[73] Thus it would appear that in the neonatal myocardium, PDE type IV may be the dominant isoenzyme that regulates intracellular calcium currents.

Structural and ultrastructural differences also exist between immature and mature hearts. These differences include reduced ventricular compliance, greater ventricular interdependence, and a reduced ratio of myocardial contractile to noncontractile protein in the immature heart. The net effect is that the immature myocardium neither responds to nor tolerates volume loading as well as the adult heart. In addition to this diminished "preload reserve," the baseline heart rate of infants and children is quite high, which limits the extent to which tachycardia can augment cardiac output before diastolic filling is compromised.

The combination of impaired preload reserve, limited chronotropic reserve, and reduced sensitivity of the heart and peripheral vasculature to adrenergic agents implies that the response of the immature organism to inotropic and vasopressor agents may differ from the pattern noted in adults.[74,75] Indeed, a recent meta-review of the use of dobutamine in pediatrics concluded that although there is evidence to support the conclusion that this drug improves cardiac output in neonates, the underlying preclinical foundation of animal research was still inadequate to define the age-related effects of dobutamine on various physiologic measures or organ systems.[76] This limitation is likely to be present in the case of the other agents

employed in pediatric critical care for the treatment of shock. Coupled with the wide variation in cardiac structure due to congenital heart disease, this means that individual differences in response to infusion of cardiovascular drugs may be difficult to predict and, to date, to explain. Meticulous observation to response must be the mainstay of safely administering these drugs to children.

Sympathomimetic Amines

Virtually all sympathomimetics currently used to treat hemodynamic problems are catecholamines. This class includes the endogenous compounds epinephrine, norepinephrine, and dopamine and the synthetic products isoproterenol and dobutamine. Catecholamines have a β-phenylethylamine core with hydroxyl (OH) substituents at the 3 and 4 aromatic ring positions (Fig. 33.8). Minor differences in molecular substitution about the N-terminus or the *α* or β carbons produce marked differences in activity. Structure-activity relationships are complex for the catecholamines and have been reviewed; it is possible to generalize by noting that increasing size of the substituent on the amino group enhances β-adrenergic activity, whereas decreasing size is associated with *α*-adrenergic selectivity.[77] Tyrosine serves as the base compound for the synthesis of catecholamines. Tyrosine hydroxylase catalyzes the conversion of tyrosine to dopa, which undergoes decarboxylation, producing dopamine. Dopamine β-hydroxylase converts dopamine to norepinephrine. In the adrenal medulla, norepinephrine is converted to epinephrine by N-methyl transferase (Fig. 33.9).

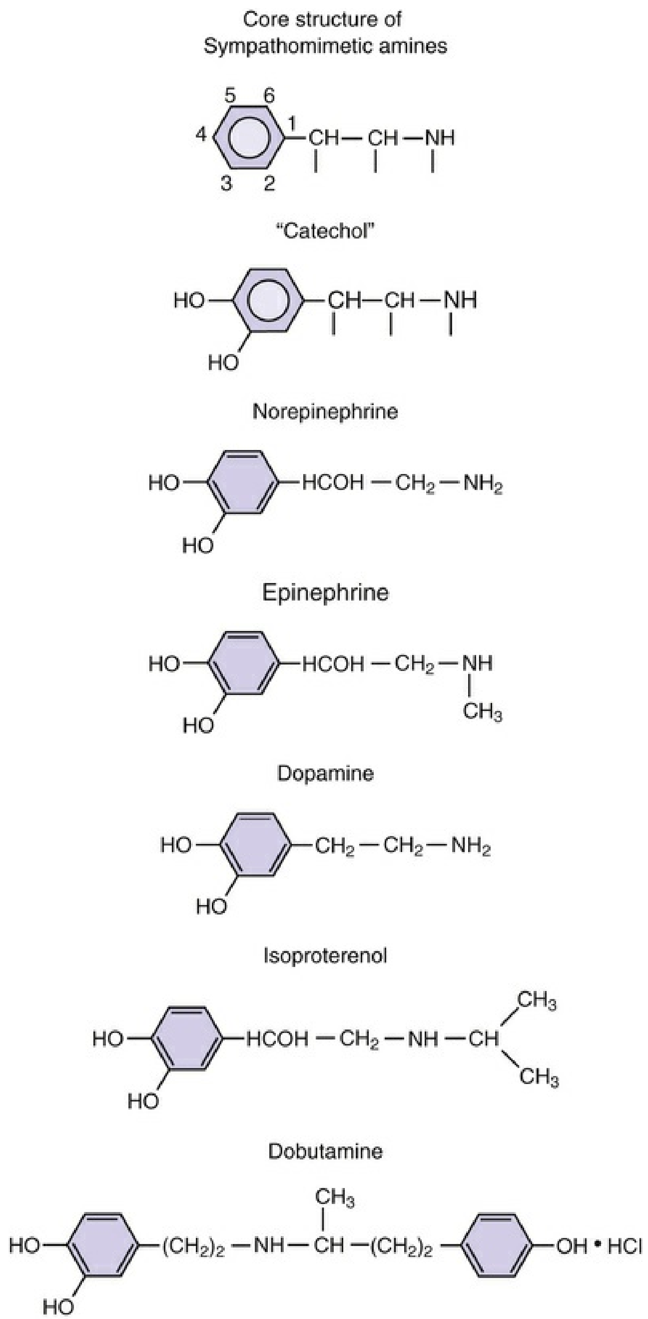

FIG. 33.8 Chemical structure of the catecholamines. (Modified from Chernow B, Rainey T, Lake R. Endogenous and exogenous catecholamines in critical care medicine. Crit Care Med. 1982;10:409.)

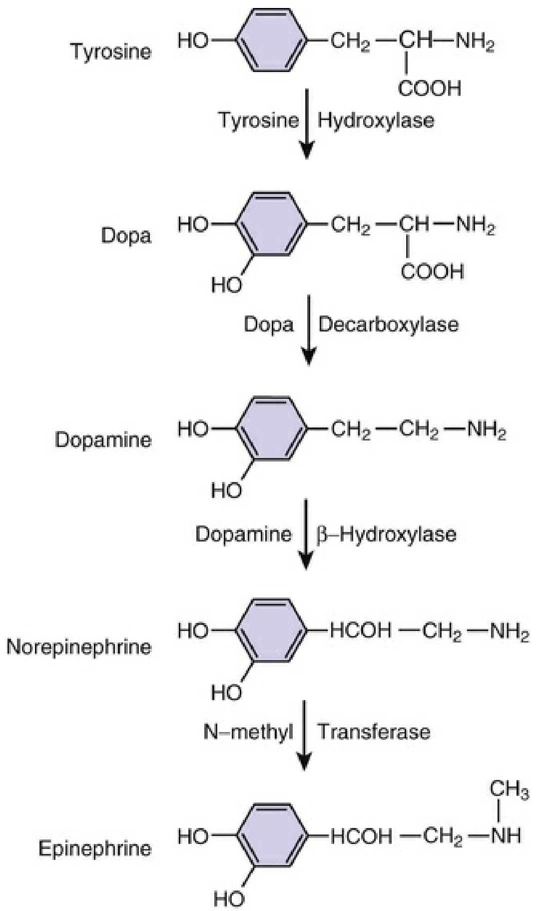

FIG. 33.9 Biosynthetic pathways of the endogenous catecholamines. (Modified from Chernow B, Rainey T, Lake R. Endogenous and exogenous catecholamines in critical care medicine. Crit Care Med. 1982;10:409.)

Catecholamines are subject to several different elimination processes.[78] Infused dopamine provides an example in which elimination occurs through a variety of processes. A small proportion is excreted unchanged in the urine. It is likely that a proportion undergoes neuronal reuptake. The principal means of elimination appears to be O-methylation by catechol O-methyltransferase (COMT) to form metanephrines, followed by either sulfoconjugation (by phenol sulfotransferase) or by deamination (by monoamine oxidase [MAO]) to homovanillic acid.[79] Substitution at the α carbon determines the rate of deamination by MAO.[80] The contribution of these pathways to total body clearance of catecholamines varies with age and the particular circulatory bed. In newborn lambs, the lungs accounted for 35% of the total body clearance of norepinephrine and 15% of the clearance of epinephrine. Inhibition of MAO by desipramine decreased pulmonary clearance to near zero and decreased total body clearance of norepinephrine and epinephrine by 51% and 30%, respectively.[81] In adult rabbits, inhibition of COMT and MAO simultaneously decreased pulmonary clearance of norepinephrine, epinephrine, and dopamine but had only minor effects on total body clearance.[82] Inhibition of COMT did not change extracellular levels of catecholamines in the CNS.[83] Furthermore, individual differences in COMT activity are not well correlated with dopamine clearance.[84] The liver and gut have been shown to clear between 30% and 52% of the circulating norepinephrine and epinephrine.[85,86] It is likely that processes or drugs that disturb these routes of elimination will decrease the overall metabolic clearance of

catecholamines. Organ dysfunction associated with critical illness is known to increase the blood concentration of dopamine during a given infusion rate of the compound. For example, with liver dysfunction the clearance of dopamine is reduced.[87]

It is practical to divide the properties of catecholamines into their inotropic and vasopressor effects. An inotropic agent increases stroke work at a given preload and afterload. Typically, these agents engage receptors of the β_1-adrenergic class. Agents that stimulate β_1-adrenergic receptors also tend to increase heart rate modestly, unless other properties of the drug prevent this increase. Some inotropic agents also activate β_2 receptors, promoting peripheral vasodilatation and reflex tachycardia. In addition, the improvement in cardiac output that these agents provide may permit a reflex relaxation of vascular tone and systemic vascular resistance.

A vasopressor agent increases peripheral vascular tone, elevating systemic vascular resistance and blood pressure. Typically, vasopressors engage α_1-adrenergic receptors, causing contraction of vascular smooth muscle. In principle, the physician will use a vasopressor agent to treat peripheral vasoplegia and an inotropic agent when the major problem is impaired cardiac contractility. In practice, most available agents display a blend of inotropic, chronotropic, and vasopressor activity that is often dose dependent. Norepinephrine has both inotropic and vasopressor effects, although it is most commonly used as a vasopressor agent. Phenylephrine (a noncatecholamine) has considerable specificity for the α-adrenergic receptor, so it is almost a pure vasopressor. Isoproterenol and dobutamine have little α-adrenergic agonist activity but considerable activity at the β receptor; they are mostly used as inotropes. Epinephrine and dopamine have both inotropic and vasopressor activity. At relatively low infusion rates, they enhance myocardial function and increase heart rate (β_1 and β_2). At higher rates, vasopressor activity (α_1) becomes manifest.

Dopamine

Basic Pharmacology

In the enzymatic pathway leading from tyrosine to epinephrine (Fig. 33.9), decarboxylation transforms L-dopa to dopamine. Dopamine is a central neurotransmitter and is also found in sympathetic nerve terminals and in the adrenal medulla, where it is the immediate precursor of norepinephrine.

Clinical Pharmacology

Dopamine stimulates dopamine (D_1 and D_2) receptors located in the brain and in vascular beds in the kidney, mesentery, and coronary arteries (Table 33.2).[88] It also stimulates α and β receptors, although the compound's affinity for these receptors is lower. D_1 receptors are coupled to G_s and thus enhance adenylate cyclase and produce a rise in cAMP, which evokes vasodilatation. This increases blood flow to these organs and enhances renal solute and water excretion by the kidney. Dopamine modulates release of aldosterone and prolactin (via D_2 receptors), which also may affect renal solute clearance.[89] The physiologic role of dopamine has been extensively reviewed.[67,90]

TABLE 33.2

Major Hemodynamic Effects of Adrenergic Receptor Activation by Catecholamines

Agent	RECEPTOR

[a]Dose related. At low infusion rates, D1 receptor effects predominate; at intermediate rates, β1 and β2 receptor effects predominate; and at high rates, α receptor effects predominate.

[b]Dose related. At low infusion rates, β receptor effects predominate; at high rates, α receptor effects predominate.

D1, dopamine receptor; *PVR*, pulmonary vascular resistance; *SVR*, systemic vascular resistance.

Modified from Notterman DA. Pharmacologic support of the failing circulation: an approach for infants and children. Prob Anesth. 1989;3:288.

Low infusion rates of dopamine augment renal sodium excretion; intermediate rates (5–10 μg/kg/min) produce chronotropic and inotropic effects, and still higher infusion rates increase vascular resistance.[91] Renal blood flow, glomerular filtration rate, and sodium excretion are maintained or even increase during dopamine infusion in patients with poor cardiac output.

Research into the dose-physiologic response relationships in patients treated with dopamine has yielded inconsistent results,[92-95] suggesting that a patient's response to a given dose depends on multiple factors, including underlying condition, hemodynamics, and adrenergic receptor status and highlighting the importance of titration to individual response when using catecholamines in the management of critically ill patients. Despite these observed variations in dose response, there is now consensus that the augmentation in urine output seen in critically ill patients with poor cardiac output who are started on low-dose, "renal" dopamine results from improved renal blood flow rather than a direct, receptor-mediated diuretic effect on the kidney. Regardless, the use of low-dose dopamine in pediatric and neonatal ICUs to augment renal function continues despite the lack of evidence to suggest a beneficial effect.[96]

Both the receptor-mediated activity and clinical effects of dopamine depend in part on developmental factors such as age and, in the case of newborns, the degree of prematurity.[97] However, as reported in adults, trials in newborns have also yielded conflicting results. Nevertheless, dopamine remains one of the most widely used vasoactive medications in the neonatal ICU amid ongoing controversies concerning the indications for pharmacologic intervention and specific therapeutic goals (ie, optimal blood pressure vs. adequate organ perfusion) in this unique population. Additionally, uncertainty persists regarding the long-term effects of dopamine on neurologic development in premature infants.[98]

While there is limited evidence to support the observation that the inotropic and peripheral vasoconstrictor effects of dopamine predominate in the neonatal period,[68]

controversies remain regarding the vasodilator effects on the renal, coronary, and cerebral vascular beds.[69] In addition, the view that infants display reduced sensitivity to dopamine is not very well supported. In support of reduced sensitivity, Perez and associates[70] found that in critically ill neonates, infusion rates greater than 20 μg/kg/min were necessary to achieve cardiovascular stability, but unlike in adults, reductions in urine output or peripheral perfusion were not observed. Much of the experimental evidence for diminished sensitivity to dopamine in infants emerged from studies in immature animals, and questions remain as to whether the results can be directly applied to humans. A contrary observation was made by Padbury and coworkers,[99] who found that dopamine at doses as low as 0.5 to 1 μg/kg/min increased cardiac output and stroke volume before heart rate, while increases in systemic vascular resistance did not occur until infusion rates exceeded 8 μg/kg/min. Seri and colleagues[97] attributed the increase in blood pressure they observed in critically ill premature infants at doses of 2.5 to 7.5 μg/kg/min to the enhanced α-adrenergic sensitivity of the immature myocardium, but reduced clearance of dopamine in this age group has also been proposed.[68]

Dopamine crosses the blood-brain barrier in preterm neonates, and in one recent study, Wong and associates[100] demonstrated improved cerebral venous saturations and coupling of cerebral blood flow to cerebral metabolic rate of oxygen consumption in 10 infants treated with dopamine when compared with 16 controls. Dopamine also inhibits the release of prolactin, thyrotropin, growth hormone, and the gonadotropins, but the clinical significance of these effects is unclear.[97,101,102]

Pharmacokinetics

Plasma dopamine clearance ranges from 60 to 80 mL/kg/min in normal adults and is lower in patients with renal or hepatic disease.[87,103] In subjects with normal renal function, the elimination half-life of infused dopamine is approximately 2 minutes.[104] Among critically ill children, the elimination half-life is 26 ± 14 minutes, and in neonates the elimination half-life is 5 to 11 minutes.[71,72] Wide interindividual variations in the rate of dopamine clearance have been reported in critically ill children and healthy adults.[105,106]Age has a striking effect on clearance of dopamine, and clearance in children younger than 2 years of age is approximately twice as rapid as it is in older children (82 vs. 46 mL/kg/min).[87] Allen and colleagues[84] demonstrated that clearance of infused dopamine decreased by almost 50% during the first 20 months of life, while an additional 50% decrease occurs between the ages of 1 and 12 years. Of note, another study did not show a correlation between advancing age and dopamine clearance, although the patients in this study had a mean age of 37 months.[105] Dopamine clearance may also decrease after 24 hours of continuous infusion.[4] Banner and colleagues[107] studied the pharmacokinetics of dopamine in 15 patients ranging in age from 3 days to 8 years and noted nonlinear behavior, and the authors questioned the utility of evaluating total body clearance in this age group. Differences in the rate of sulfoconjugation as a route of elimination may also contribute to the wide variations in the clearance of dopamine in critically ill children.[84,87,105] The possible role of concomitantly administered dobutamine on the clearance of dopamine has been suggested by some authors, but an in vitro study showed that although dopamine and dobutamine are competitors for both COMT and MAO, the concentrations achieved under clinical situations are unlikely to produce clinically significant levels of inhibition.[72,108] Pharmacokinetic differences

between children and infants, rather than a difference in vascular or myocardial receptor sensitivity, may account for the observation that infants require and tolerate higher infusion rates. For a more detailed discussion on the pharmacokinetics of dopamine and other cardiovascular drugs, the reader is directed to one of many comprehensive reviews.[109]

Clinical Role

Dopamine has been shown to be an effective inotropic and vasopressor agent in neonates and infants with a variety of conditions associated with circulatory failure, including hyaline membrane disease, asphyxia, sepsis syndrome, and cyanotic congenital heart disease.[110,111] Fewer data evaluating the efficacy of dopamine in older children are available. However, it remains a mainstay of pharmacologic support for the child with inadequate perfusion. Dopamine may be used in children with fluid refractory septic shock or distributive shock,[112-114] but this topic is debated, and many practitioners favor the use of norepinephrine or epinephrine. Dopamine may also be appropriate for children with mild impairment of myocardial function and hypotension after resuscitation from cardiac arrest.[115,116] Severe impairment of vascular tone or of cardiac contractility suggests the need for other agents. Children with primary myocardial disease not complicated by frank hypotension will benefit from a more selective inotropic agent such as milrinone or dobutamine. Infusion rates of dopamine needed to improve signs of severe myocardial dysfunction may be associated with tachycardia, dysrhythmia, and increased myocardial oxygen consumption, and these adverse effects may outweigh any improvement in myocardial perfusion.

Adverse Effects

The clinical signs of dopamine toxicity are mainly cardiovascular: tachycardia, hypertension, and dysrhythmia. However, dopamine is less likely to produce severe tachycardia or dysrhythmias than either epinephrine or isoproterenol.[117] With the possible exception of the bipyridines, all inotropes increase myocardial oxygen consumption because they increase myocardial work. If the resulting increase in oxygen consumption is balanced by improved coronary blood flow, the net effect on oxygen balance is beneficial. The effect of dopamine on myocardial oxygen balance is better than that of isoproterenol, but not as good as dobutamine, and milrinone.[118] In the setting of cardiogenic shock, the improvement in myocardial contractility with the addition of an inotrope may reduce preload and afterload, improve coronary perfusion pressure, increase myocardial oxygen supply, and prolong diastolic coronary perfusion by reducing heart rate. If the same drug is administered to a patient with normal myocardial contractility, the result may be an increase in cardiac oxygen consumption without an increase in oxygen delivery to the myocardium. Tachycardia, due to both increasing oxygen consumption and shortening diastole, is a particular burden.

Dopamine depresses the ventilatory response to hypoxemia and hypercarbia by as much as 60%.[119] Dopamine (and other β agonists) decrease PaO_2 by interfering with hypoxic vasoconstriction.[120] In one study, dopamine increased intrapulmonary shunting in patients with acute respiratory distress syndrome (ARDS) from 27% to 40%.[121] The effect of dopamine on perfusion to the splanchnic bed is widely debated.

Evidence suggests that in patients with sepsis dopamine may increase splanchnic blood flow and gastric pH and lead to less lactate production than epinephrine.[122-125] Dopamine may also increase oxygen delivery and reduce oxygen consumption in septic patients.[126,127] On the other hand, experiments in animals suggest that dopamine is capable of modulating cellular immune functions in sepsis and may decrease survival. In a murine model, survival in dopamine-treated septic animals decreased by nearly 40%.[128] An increase in splenocyte apoptosis and decrease in splenocyte proliferation and IL-2 release, both of which indicate attenuated immune system function, were also observed.

In infants and children who have undergone cardiac surgery, dopamine may have several endocrinologic effects including decreases in prolactin and thyrotropin levels, as well as a reduction in the pulsatility of growth hormone.[89]

In patients with shock, dopamine can cause or worsen limb ischemia, gangrene of distal parts and entire extremities, and extensive loss of skin.[129] This is due to release of norepinephrine from synaptic terminals and in vivo conversion to norepinephrine. Hence, it is more often associated with limb ischemia than other adrenergic compounds. Extravasations of dopamine should be treated immediately by local infiltration with a solution of phentolamine (5–10 mg in 10 mL of normal saline solution) administered with a fine hypodermic needle.[130]

Preparation and Administration

Dopamine hydrochloride is available as premixed solutions in 5% dextrose or normal saline for infusion.[71] The use of standard concentrations and electronic "drip calculators"[131] is encouraged to prevent dosing errors. Dopamine is administered by central vein to avoid the risk of skin injury from extravasation, although it can be given safely through a peripheral intravenous catheter while central access is being secured. Dopamine may also be administered via the intraosseous route.[132] Table 33.3 provides information regarding compatibility.[133,134] Dopamine is not compatible with some of the 3-in-1 solutions used for parenteral nutrition or with sodium bicarbonate.[135] Dopamine is stable in solution for 24 to 84 hours.[136,137]

[a]Norepinephrine = More stable in D5W at higher concentrations because of its high level of acidity (pH 3)

C, compatible; *C/I,* may be unstable at higher concentrations of additives; *C/NS,* this combination is more stable in normal saline solution (NS) than in D5W because of an exothermic reaction; *I,* incompatible.

From Trissel LA. Handbook on Injectable Drugs. 15th ed. Bethesda, MD: American Society of Health-System Pharmacists; 2009.

Interactions

Dopamine is metabolized by MAO, and concurrent use of an MAO inhibitor potentiates its effect.[77] In this rare circumstance, the initial dosage of dopamine should be reduced to one-tenth the usual dosage.[138] Both α-adrenergic blockers and β-adrenergic blockers antagonize the effects of dopamine. Other dopamine antagonists such as metoclopramide or haloperidol also may attenuate its effects. An increase in the infusion rate will often overcome the receptor blockade.

Summary

Dopamine is used to treat mild to moderate cardiogenic or distributive (septic, hypoxic-ischemic) shock associated with moderate degrees of hypotension. In the absence of hypotension, acute severe cardiac failure is treated with dobutamine or milrinone. When septic or cardiogenic shock is complicated by severe hypotension, epinephrine or norepinephrine is preferred, depending on hemodynamics and myocardial function (Table 33.4).

TABLE 33.4

Selecting Inotropic and Vasopressor Agents for Specific Hemodynamic Disturbances in Children

Hemodynamic Pattern	BLOOD PRESSURE OR SVR		
	Normal	**Decreased**	**Elevated**
Septic Shock			
Stroke index ↑ or ↔		Norepinephrine	
Stroke index ↓	Dobutamine or dopamine	Dopamine or epinephrine (or dobutamine and norepinephrine)	Dobutamine plus vasodilator and/or PDIII inhibitor

Norepinephrine

Basic Pharmacology

Dopamine is hydroxylated at the β carbon to produce norepinephrine, the principal neurotransmitter of the sympathetic nervous system (Figs. 33.8 and 33.9). Because there is no substituent on the N (amino)-terminus, norepinephrine has little β_2 activity and is considerably less potent at that receptor than epinephrine.[77] It is a moderately potent α and β_1 agonist.

Clinical Pharmacology

In normal subjects, norepinephrine elevates systemic vascular resistance (SVR) because α-adrenergic stimulation is not opposed by β_2 stimulation.[77] Reflex vagal activity reduces the rate of sinus node discharge, thereby blunting the expected β_1 chronotropic effect. In normal subjects renal, splanchnic, and hepatic blood flows decrease. The increase in afterload may augment coronary blood flow. This effect may be enhanced by α-adrenergic receptors located in the coronary arteries, although in coronary arteries from explanted human hearts, the vasodilatation in response to norepinephrine was mediated via β_2 receptors.[139] Norepinephrine does have inotropic effects on the heart, mediated via α_1 and β_1 receptors. The proportion of inotropic response related to α_1 stimulation may be affected by the pressure load on the right ventricle.[140] In the failing heart, the relative contribution from each type of adrenergic receptor appears to be equal.[141] In the isolated rat heart, the inotropic effects of norepinephrine are diminished in the presence of a nitric oxide synthetase inhibitor but restored when a nitric oxide donor is present.[142] In healthy volunteers norepinephrine produces a decrease in creatinine clearance because of the effect on renal blood flow; however, in patients with hypotension, the improvement in global perfusion produces an increase in urine output.[143]

The acute hemodynamic effects of norepinephrine are compared with those of epinephrine and isoproterenol in Fig. 33.10. Experience in critically ill children indicates that the hemodynamic responses are not different from those observed in adults. Use of norepinephrine in 18 neonates with persistent pulmonary hypertension–associated heart dysfunction produced significant increases in systemic blood pressure (33 ± 4 to 49 ± 4 mm Hg; P <.05) and LV output (172 ± 79 to 209 ± 90 mL/kg/min; P <.05), along with improvement in postductal transcutaneous oxygen saturation (89% ± 1% to 95% ± 4%; P <.05), pulmonary-to-systemic blood pressure ratio (0.98 ± 0.1 to 0.87 ± 0.1; P <.05), and a 20% increase in the velocity of pulmonary artery blood flow (P <.05).[144] In a separate study in 22 neonates with septic shock refractory to fluid support and dopamine or dobutamine, norepinephrine (mean infusion rate 0.5 ± 0.4 μg/kg/min) significantly increased mean arterial blood pressure (36 ± 5 to 51 ± 7 mm Hg; P <.001) and urine output (1 ± 0.5 to 1.7 ± 0.4 mL/kg/hr; P <.05) while decreasing blood lactic acid concentrations (4.8 ± 2.3 to 3.3 ± 1.8 mmol/L; P <.01).[145]

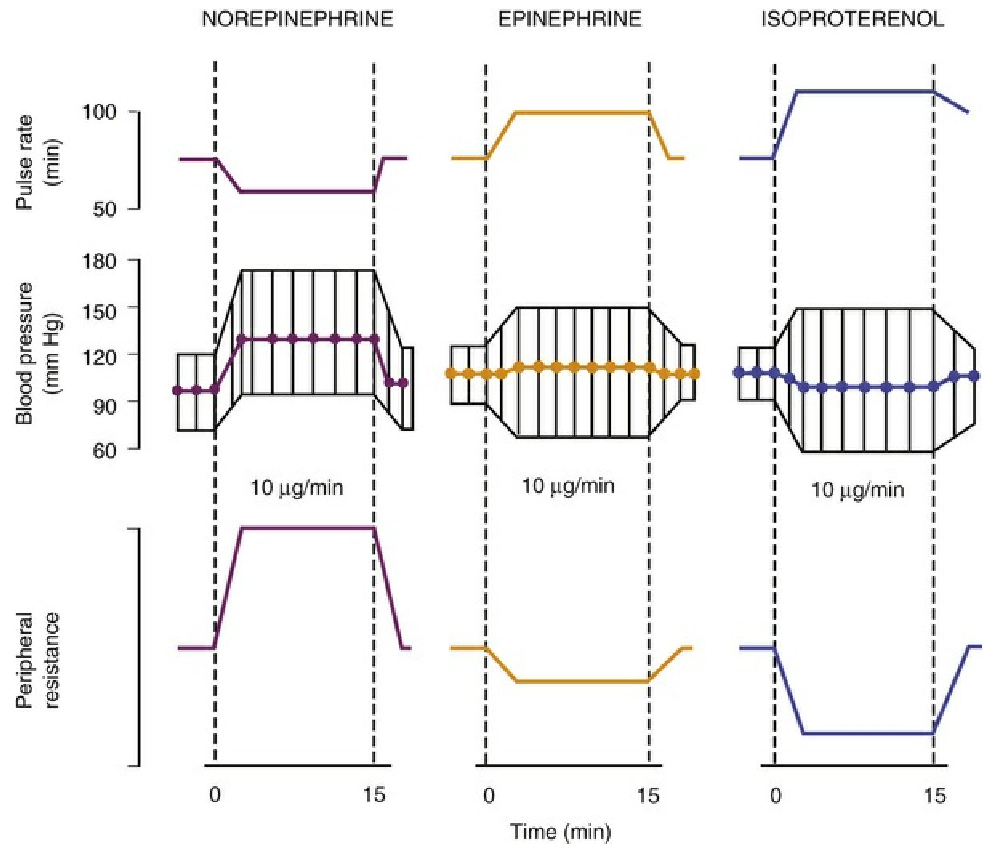

FIG. 33.10 Effects of intravenous infusion of norepinephrine, epinephrine, and isoproterenol in adult humans. (Modified from Allwood MJ, Cobbold AF, Ginsberg J. Peripheral vascular effects of noradrenaline, isopropylnoradrenaline and dopamine. Br Med Bull. 1963;19:132.)

Pharmacokinetics

Basal plasma levels of norepinephrine are much higher than basal plasma levels of epinephrine (250–500 vs. 20–60 pg/mL). The minimum concentration at which norepinephrine produces detectable hemodynamic activity is at least 1500 to 2000 pg/mL, suggesting that endogenous plasma norepinephrine simply represents "spillover" from sympathetic activity and that norepinephrine is not a true hormone.[146] The clearance of norepinephrine in healthy adults is 24 to 40 mL/kg/min, with the half-life averaging 2 to 2.5 minutes.[147] The clinical effect of norepinephrine ceases within 2 minutes of the infusion being stopped.[147] Little pharmacokinetic information in children is available. Norepinephrine is inactivated by reuptake into nerve terminals, with some elimination occurring by enzymatic degradation in the liver, adrenal glands, and kidney, either by methylation to normetanephrine (by COMT) or by oxidative deamination.[148] Most of the metabolites formed by either MAO or COMT are then reduced or oxidized further. 3-Methoxy-4-hydroxymandelic acid is the major metabolite in the urine.[77]

Clinical Role

Norepinephrine improves perfusion in children with low blood pressure and a normal or elevated cardiac index. Distributive or septic shock is the usual context in which norepinephrine is beneficial. Norepinephrine is administered in conjunction

with repletion of intravascular volume and is best guided by estimates of cardiac output and SVR. The experience in adult patients provides a rationale for using this agent to treat hypotension that is unresponsive to volume repletion,[149-152] and norepinephrine is now a recommended agent for warm shock refractory to fluid loading in children as well.[114,153] A prospective, unblinded randomized study (in adults) indicates that high-dose norepinephrine is superior to high-dose dopamine for treating hypotension and other hemodynamic abnormalities associated with hyperdynamic septic shock.[154] Others have reported that lower average dosages (0.4 μg/kg/min) were effective in adults with sepsis.[155] Coronary and renal blood flow increased in lambs at a dose of 0.4 μg/kg/min while mesenteric blood flow decreased.[156] Thus titration is important and may entail fairly rapid escalation of dosage. One of several studies in children with septic shock treated with norepinephrine suggested that higher doses might be necessary in this population to restore adequate blood pressures and perfusion. A single-center retrospective review of 144 children with septic shock treated with norepinephrine between 2000 and 2010[157] reported a decrease in mortality from 82% to 17% over the study period and an associated increase in norepinephrine use. Mean doses ranged from 0.5 mcg/kg/min to 2.5 mcg/kg/min. The only complications observed were arrhythmias (not requiring treatment) in two patients and hypertension, which resolved with lowering of the norepinephrine dose. Notably, the authors reported no complications in 27 patients receiving the drug through a peripheral intravenous catheter for periods as long as 3 hours. Though the findings from this study suggest that norepinephrine is safe and effective for reversal of hypotension and hypoperfusion in the context of septic shock, the authors caution that prospective studies are necessary to determine when and how norepinephrine should be used in this patient population.

Norepinephrine produces increases in SVR, arterial blood pressure, and urine flow. It is most valuable in the context of tachycardia because unlike dopamine at doses required to induce a vasopressor effect, norepinephrine does not produce significant elevation and may even lower heart rate through reflex mechanisms. In a study of adults with abdominal sepsis, norepinephrine infusion was associated with increases in systemic blood pressure and SVR. Stroke volume increased as heart rate declined. Cardiac index did not change, although creatinine clearance increased substantially.[155] Norepinephrine has also been shown to improve right ventricular (RV) performance in adults with hyperdynamic septic shock.[154]

The usual starting dosage for an infusion is 0.1 μg/kg/min (Table 33.5), with a goal of elevating perfusion pressure so that the flow to vital organs is above the threshold needed to meet metabolic requirements.[158] Arbitrary values of SVR or blood pressure are not appropriate end points for therapy, and the lowest infusion rate that improves perfusion as judged by clinical indices such as skin color and temperature, mental status, urine flow, and reduction in plasma lactate level should be used.[159]

TABLE 33.5

Suggested Infusion Rates for Inotropic and Vasopressor Agents (μg/kg/min)

Agent	CLINICAL INDICATION

Isoproterenol	0.05-1	

[a]Units/kg/min.

[b]The optimal dosage and infusion rates have not been established in children.

Other causes of distributive shock (eg, vasodilator ingestion, intoxication with CNS depressants) also respond to norepinephrine when the predominant hemodynamic problem is low SVR and blood pressure.

Adverse Effects

The increase in afterload that norepinephrine produces can potentially increase myocardial oxygen consumption, but norepinephrine may reflexively decrease heart rate, thereby reducing oxygen consumption and improving diastolic coronary perfusion.[77] Norepinephrine may lead to compromised organ blood flow in the setting of hypovolemia. Norepinephrine infusion may elevate blood pressure yet not improve clinical indices of perfusion. Poor clinical response is usually associated with a low cardiac index, stroke volume, LV stroke work index, and an elevated pulmonary artery occlusion pressure.[149,150] Employing excessive dosages or using norepinephrine to elevate blood pressure without improving perfusion may result in multiple organ system failure.

Preparation and Administration

See Table 33.3 for information regarding compatibility. Norepinephrine bitartrate is available in 4-mL ampules at a concentration of 1 mg/mL.[147] Norepinephrine should be diluted in 5% dextrose or 5% dextrose in 0.9% sodium chloride for preparation of infusions. Norepinephrine is administered only by central venous catheter, except in extreme emergency. Extravasation of norepinephrine should be treated immediately by local infiltration with a solution of phentolamine (5–10 mg in 10 mL of normal saline solution) administered with a fine hypodermic needle.[130,147] As with dopamine, norepinephrine should be administered by a syringe pump or other device that permits controlled and precise titration.

Interactions

Tricyclic antidepressants potentiate the action of norepinephrine by reducing neuronal uptake of the compound.[147] MAO inhibitors do not appear to enhance the activity of infused norepinephrine. α-Adrenergic blocking agents reduce efficacy of norepinephrine.

Summary

Norepinephrine is the agent of choice when the principal hemodynamic disturbance involves hypotension with an abnormally low SVR and a normal or high cardiac output after fluid resuscitation (Table 33.4). The most recent septic shock guidelines recommend norepinephrine as the “first choice” vasopressor in patients with warm (vasodilatory) shock.[114] It is frequently useful in other conditions associated with distributive shock.

Epinephrine

Basic Pharmacology

Epinephrine is synthesized in the adrenal medulla where it is formed from norepinephrine by addition of a methyl group to the N-terminus.[117] The reaction is catalyzed by N-methyl transferase (see Fig. 33.9). Epinephrine is a hormone, and endogenous levels change with the physiologic state of the organism via afferent input to the adrenal medulla. Resting levels are less than 50 pg/mL; heavy exercise produces concentrations of 400 pg/mL or greater.[146] In a group of critically ill children not receiving catecholamines, epinephrine levels between 0 and 1378 pg/mL at admission (mean, 508 pg/mL) have been reported.[160,161] Epinephrine activates α, β_1, and β_2 receptors. It is a principal hormone of stress and produces widespread metabolic and hemodynamic effects, which have been extensively reviewed.[117]

Clinical Pharmacology

β_1 receptors are affected by very low concentrations of epinephrine; consequently, one of the early effects of epinephrine infusion is activation of β_1 receptors in the myocardium and conducting systems, which accelerates phase 4 of the action potential. The rate of sinoatrial node discharge and heart rate increase, and systolic time intervals are shortened. The inotropic state of the myocardium is also enhanced, producing an increase in force of contraction and rate of rise of pressure. Evidence indicates that myocardial oxygen consumption is out of proportion to the increase in force of contraction, decreasing myocardial efficiency.[117] High concentrations of epinephrine or exposure to the compound when the myocardium is sensitive because of infarction, operation, or myocarditis may produce serious atrial and ventricular dysrhythmias.[117]

At low plasma concentrations, stimulation of peripheral β_2 receptors promotes relaxation of resistance arterioles; SVR decreases and diastolic blood pressure falls (Fig. 33.10). The decrease in SVR enhances the direct chronotropic effect of epinephrine. Higher concentrations are associated with activation of vascular α receptors, and SVR increases. The effect of epinephrine on the pulmonary vasculature may also vary as a result of the dosage used.[162] Higher doses are also associated with an increase in pulmonary vascular resistance (PVR), both from a direct effect and as a result of increased venous return to the right side of the heart.[117] During infusion of epinephrine, hepatic and splanchnic blood flow increase, while renal blood flow may be reduced.[117]

The thresholds for producing these effects in healthy adults have been examined.[146] Normal basal levels are around 40 pg/mL. Heart rate accelerates between 50 and 100 pg/mL; changes in blood pressure (systolic blood pressure increases, diastolic blood pressure decreases) occur between 75 and 100 pg/mL. Various metabolic effects (hyperglycemia, cytogenesis, and glycolysis) occur between 150 and 200 pg/mL. Concentrations of this magnitude are achieved during therapeutic infusion of the drug. Other metabolic effects include hypophosphatemia and hypokalemia. Desensitization to elevated levels of epinephrine occurs rapidly and may be present before administration of exogenous catecholamines in the ICU.

Pharmacokinetics

In healthy male volunteers the plasma clearance of epinephrine is 35 to 89 mL/kg/min.[163,164] The elimination half-life is approximately 1 minute.[104] Epinephrine is methylated by COMT to metanephrine in the liver and kidneys or deaminated via the action of MAO.[72] It also may be metabolized by extraneuronal uptake.[148] The resulting catabolites are then conjugated to sulfate or glucuronide and excreted in the urine. A wide interindividual variation in clearance is observed in healthy adults. In critically ill children receiving epinephrine at doses from 0.03 to 0.2 μg/kg/min, plasma concentrations at steady state ranged from 0.67 to 9.4 ng/mL and were linearly related to dose.[161] In this study, clearance ranged from 15 mL/kg/min to 79 mL/kg/min, demonstrating wide interindividual variation similar to dopamine. Variability between the ordered and the measured dose of catecholamines has also been observed.[165] Combined with the interindividual variation in clearance, there may be significant differences in plasma concentrations between patients receiving the “same” dose of epinephrine or dopamine.

Clinical Role

Epinephrine is employed to treat shock associated with myocardial dysfunction. Thus it is appropriate for treatment of cardiogenic shock or for inotropic support following cardiac surgery.[140] In a model of RV injury, epinephrine increased pulmonary artery blood flow and RV power with greater efficiency than did dopamine or dobutamine.[162] It can also be used to increase pulmonary flow across left-to-right shunts.[89] The patient with sepsis who continues to manifest cool extremities after intravascular volume repletion may benefit from an infusion of epinephrine. Epinephrine is most likely to be useful when hypotension exists in the context of a low cardiac index and stroke index (“cold shock”).[112] At modest infusion rates (0.05–0.1 μg/kg/min), SVR decreases slightly; heart rate, cardiac output, and systolic blood pressure increase. At intermediate infusion rates, α_1-adrenergic activation becomes important but is balanced by the improved cardiac output and activation of vascular β_2 receptors. Even though epinephrine constricts renal and cutaneous arterioles, renal function and skin perfusion may improve. Very high infusion rates (more than 1–2 μg/kg/min) are associated with significant α_1-adrenergic–mediated vasoconstriction; blood flow to individual organs will be compromised, and the associated increase in afterload may further impair myocardial function. The effects of epinephrine on splanchnic blood flow continue to be investigated. Studies have shown decreased splanchnic blood flow, decreased oxygen uptake, and increased lactate with epinephrine compared with norepinephrine despite similar increases in global oxygen delivery.[166] Dopamine led to a decrease in lactate and an increase in arterial pH, whereas epinephrine was associated with increases in lactate and metabolic acidosis despite similar increases in cardiac index and oxygen delivery.[122] At a dose of 3.2 μg/kg/min in newborn piglets, epinephrine increased SVR and PVR, with a decrease in hepatic blood flow and oxygen delivery and an increase in lactate.[167] These effects were likely the result of the high dosages used and impaired hepatic utilization of lactate. Seguin and colleagues[168] demonstrated increased gastric blood flow with epinephrine compared with the combination of norepinephrine and dobutamine. They note that the doses of norepinephrine they used were higher than in previous studies. Other studies have shown that the degree of shock also may influence splanchnic blood flow.[169] In

a study involving adult patients with septic shock, stepwise infusion of epinephrine was associated with linear increases in cardiac rate, mean arterial pressure, cardiac index, LV stroke work index, oxygen consumption, and oxygen delivery. In that study, neither pulmonary nor systemic vascular resistance was affected by epinephrine infusion.[79] Epinephrine is first-line treatment for severe anaphylaxis in both the prehospital and hospital settings. Although controlled studies cannot ethically be conducted, the case-fatality rate from food-related anaphylaxis has declined since the introduction of the epinephrine autoinjector.[170]

Epinephrine has been evaluated in very low-birth-weight infants with hypotension that did not respond to dopamine at doses as high as 15 μ/kg/min.[171] Blood pressure and heart rate increased while urine output was maintained. In fact, urine output increased among infants who had been oliguric.

Epinephrine is the most frequently used medication during pediatric cardiopulmonary resuscitation. Bolus injections of epinephrine are used to treat hemodynamically significant bradycardia, asystole, and pulseless arrest. Earlier studies in animals[172,173] demonstrated improved survival after primary cardiac arrest in subjects treated with epinephrine. This was attributed to higher rates of return of spontaneous circulation associated with improved coronary (and therefore myocardial) perfusion from an increase in aortic diastolic pressure. A study in adults following cardiopulmonary arrest attributed to ventricular fibrillation showed that early use of epinephrine was associated with improved survival to hospital discharge, while later initiation of the drug was not.[174,175] The recommended initial dosage is 0.01 mg/kg (10 μg/kg or 0.1 mL/kg of the 1 : 10,000 solution).[176] High-dose epinephrine (1 : 1000 concentration) is no longer recommended after clinical trials in adults and children comparing high-dose with standard-dose epinephrine showed no benefit in return of spontaneous circulation and possible decrease in 24-hour survival associated with the higher dose.[177-179]

Epinephrine may be given by endotracheal tube; the dosage is 100 μg/kg. Intraosseous administration is appropriate for both bolus and continuous administration of epinephrine. The dosage is the same as for IV injection. Epinephrine by infusion is also the agent of choice for hypotension or shock following successful treatment of cardiac arrest. Shock following an episode of hypoxemia or ischemia is usually cardiogenic and often responds to epinephrine.

Preparation and Administration

Epinephrine for injection at a concentration of 1 : 10,000 injection may be administered undiluted. The 1 : 1000 injection must be diluted with 0.9% sodium chloride for injection before administration. For continuous infusion, epinephrine should be diluted to a standard concentration, often 4 μg/mL.[176] Epinephrine should be infused by a pump capable of precise titration (eg, syringe pump) into a central vein, although low-dose infusions may be administered safely via peripheral intravenous catheters if central venous access is not available. Consult Table 33.3 for compatibility information.

Adverse Effects

Epinephrine produces CNS excitation manifested as anxiety, dread, nausea, and dyspnea.[118] Enhanced automaticity and increased oxygen consumption are the main

serious cardiac toxicities.[117] Extreme tachycardia carries a substantial oxygen penalty, as does hypertension. A severe imbalance of myocardial oxygen delivery and oxygen consumption produces characteristic electrocardiogram changes of ischemia. A subischemic but persistently unfavorable ratio of oxygen delivery to consumption may also be harmful to the myocardium. This has not been adequately examined in critically ill children. Epinephrine may be arrhythmogenic. Increases in infusion rate lead to successively more serious events, including atrial and ventricular extrasystoles, atrial and ventricular tachycardia, and, ultimately, ventricular fibrillation. Ventricular dysrhythmias in the pediatric age group are not common but may occur in the presence of myocarditis, hypokalemia, or hypoxemia. Hypokalemia is produced by the infusion of epinephrine through stimulation of β_2-adrenergic receptors, which are linked to sodium-potassium-ATPase located in skeletal muscle.[180] Infusion of 0.1 μg/kg/min lowered serum potassium by 0.8 mEq/L. Hyperglycemia results from β-adrenergic–mediated suppression of insulin release. Increases in blood lactate levels have also been observed.[181] Epinephrine is an α_1-adrenergic agonist, and infiltration into local tissues or intraarterial injection can produce severe vasospasm and tissue injury.[117] Concurrent activation of β_2 receptors by epinephrine limits vasospasm, and local injury to tissue is less frequent than with norepinephrine, dopamine, or vasopressin.

Epinephrine overdose is serious. Several neonates died when inadvertently subjected to oral administration of huge amounts of epinephrine.[182] The syndrome mimicked an epidemic of neonatal sepsis with shock and metabolic acidosis. Intraaortic injection in infants (per umbilical artery) produces tachycardia, hypertension, and renal failure. IV overdose of epinephrine is immediately life threatening. Manifestations include myocardial infarction, ventricular tachycardia, extreme hypertension (up to 400/300 mm Hg), cerebral hemorrhage, seizures, renal failure, and pulmonary edema. Bradycardia also has been observed. Manifestations of acute overdose are treated symptomatically. β-receptor antagonists such as propranolol are contraindicated (see later). Hypertension is treated with short-acting antihypertensives (eg, nitroprusside).

Interactions

Tricyclic antidepressants and antihistamines such as diphenhydramine may potentiate the effects of epinephrine; use of fluorinated anesthetic agents such as halothane may increase the frequency of ventricular dysrhythmia.[117,183–185] Administration of epinephrine with a β-adrenergic antagonist such as propranolol may be dangerous because of residual unopposed α_1 activity; the result can be severe hypertension and bradycardia terminating in asystole. The concomitant use of α- or β-adrenergic antagonists also may antagonize the therapeutic effects of epinephrine.

Summary

Epinephrine is useful in treating shock associated with myocardial dysfunction and hypotension. In pediatric critical care, the most frequent indications for epinephrine infusion are resuscitation from cardiogenic shock, septic shock associated with hypotension and reduced stroke volume, and shock following severe hypoxemia-ischemia (Table 33.4).

Isoproterenol

Basic Pharmacology

Isoproterenol is the synthetic N-isopropyl derivative of norepinephrine (see Fig. 33.8). The bulky N-terminal substituent confers β_1- and β_2-receptor specificity; the compound does not affect the α-adrenergic receptor. Thus the principal cardiovascular activities of isoproterenol relate to its inotropic, chronotropic, and peripheral vasodilator effects.[117]

Clinical Pharmacology

Isoproterenol enhances cardiac contractility and heart rate.[117] Peripheral vasodilatation produces a fall in SVR, augmenting the direct chronotropic action of the drug. Significant tachycardia ensues. Systolic blood pressure increases while mean and diastolic pressures fall (see Fig. 33.10). If they were normal before infusion of isoproterenol, mesenteric and renal perfusions fall; however, if the subject was in shock, then the increase in cardiac output associated with isoproterenol administration may result in an increase in blood flow to these tissues.[117] Isoproterenol increases myocardial demand for oxygen and decreases supply by reducing diastolic coronary filling. In patients whose intravascular volume is not replete, hypotension may complicate initiation of isoproterenol infusion.

Pulmonary bronchial and vascular bed β_2-adrenergic receptors produce bronchodilation and pulmonary vasodilatation, respectively.[186] For this reason isoproterenol by continuous IV infusion was employed as adjunctive therapy in children with refractory or rapidly worsening status asthmaticus.[49] Continuously nebulized albuterol and IV infusion of terbutaline have supplanted isoproterenol for this indication.

Isoproterenol has few important metabolic effects. Hyperglycemia is not usually observed, although the drug does promote release of free fatty acids. Isoproterenol infusion causes sympathetic neurons to release norepinephrine, producing an increase in plasma levels; however, this effect relative to the hemodynamic response to isoproterenol has not been studied.[148]

Pharmacokinetics

Isoproterenol is metabolized by COMT.[117] The plasma elimination half-life of isoproterenol is 1.5 to 4.2 minutes.[187,188] Information about therapeutic isoproterenol concentrations in critically ill patients is not available. In healthy volunteers, tachycardia and increases in stroke volume were observed at 50 pg/mL.[148]

Clinical Role

In the past, isoproterenol was used for a variety of indications, including septic shock and cardiogenic shock associated with myocardial infarction; however, the tachycardia and increased myocardial oxygen consumption associated with its use, as well as a more sophisticated understanding of the pathophysiology of shock, have limited the use of this compound to very few specific indications.

Isoproterenol may be used to treat hemodynamically significant bradycardia.[189] However, epinephrine is probably preferable.[158] When bradycardia results from heart block, placement of a pacemaker is definitive treatment, but isoproterenol may

be used in the acute setting as a bridge to pacemaker placement. Bradycardia due to anoxia will respond to oxygen and improving gas exchange.

Preparation and Administration

Before administration, isoproterenol should be diluted with 0.9% sodium chloride or D5W to a standard concentration, often 4 μg/mL.

Adverse Effects

Adverse effects associated with isoproterenol include fear, anxiety, restlessness, insomnia, and blurred vision.[190] Other effects may include headache, dizziness, tinnitus, sweating, flushing, pallor, tremor, nausea, vomiting, and asthenia. Cardiovascular effects may include ventricular tachycardia and other ventricular dysrhythmias that may be life threatening. Isoproterenol may cause hypertension and also can cause severe hypotension.

Interactions

The concomitant administration of a halogenated general anesthetic such as halothane or an IV methylxanthine such as aminophylline may potentiate the adverse cardiovascular effects of isoproterenol.[190] Propranolol given before an operation to repair tetralogy of Fallot attenuates the response to isoproterenol postoperatively.[191] Although it is no longer used regularly in the treatment of asthma, isoproterenol decreases serum theophylline concentrations, and it may be necessary to increase theophylline dosage when isoproterenol therapy is initiated and reduce theophylline dosage when isoproterenol is discontinued.[192]

Summary

Isoproterenol is rarely used to treat children or adults. More selective β_2 agonists are safer to use and are preferred. In the acute setting, it may play a role in the treatment of symptomatic bradycardia.

Dobutamine

Basic Pharmacology

The structure of dobutamine, a synthetic catecholamine, resembles dopamine in that the β carbon is not hydroxylated. Unlike other catecholamines, there is a large aromatic substituent on the N-terminus. Like isoproterenol, dobutamine is administered as a racemate; (+) dobutamine is a strong β agonist and an *α* antagonist, and (–) dobutamine is an *α* agonist and a weak β agonist.[193] This blend of receptor activities allows dobutamine to deliver significant inotropic and usually trivial chronotropic and vasopressor activity.

Clinical Pharmacology

In adults with CHF, dobutamine increased cardiac index from 2.4 to 2.9 L/min/m, decreased LV end-diastolic volume, and increased the LV dP/dt.[194] Although renal function and urine output may improve as the increase in cardiac output fosters relaxation of sympathetic tone and improved perfusion, dobutamine did not improve indices of renal function compared with dopamine in critically ill patients.[195] Dobutamine improved RV systolic function and decreased PVR in piglets

with RV injury.[162] In healthy children, dobutamine increased LV systolic function and relaxation.[196] In the newborn piglet, dobutamine increased superior mesenteric and renal artery blood flow after 60 minutes, increased cardiac index, and decreased SVR.[197] A threshold model with a log-linear dose-response relationship above the threshold has been demonstrated in critically ill term and preterm neonates and in children between 2 months and 14 years of age.[105,198] In one small study, dobutamine infusion (10 μg/kg/min) was associated with increases in cardiac output (30%), blood pressure (17%), and heart rate (7%). The plasma concentration thresholds for these increases were 13, 23, and 65 ng/mL, respectively, demonstrating that dobutamine is a relatively selective inotrope with little effect on heart rate at customary infusion rates.[199] Somewhat greater thresholds for improved cardiac output were observed in a second group of children and in infants, but in all studies, dobutamine improved cardiac contractility without substantially altering heart rate unless high infusion rates were employed.[198,200] In a Cochrane analysis that compared dobutamine with dopamine in premature neonates with low systemic blood flow on the first day of life,[201] dobutamine produced a significantly greater increase in superior vena cava flow, whereas dopamine produced a significantly greater increase in mean blood pressure. In addition, dobutamine has been shown to increase cerebral blood flow velocity but not cerebral oxygen consumption in patients with septic shock.[202]

Pharmacokinetics

The plasma elimination half-life of dobutamine in adults is approximately 2 minutes.[104] CHF increases the volume of distribution. In adults with CHF the terminal elimination half-life ($t_{1/2}\beta$) of dobutamine has been reported to be 2.37 minutes, with an apparent volume of distribution of 0.2 L/kg and total body clearance of 2.33 L/min/m^2.[203] Reported clearance values in children have ranged from 32 to 625 mL/kg/min in one study and from 40 to 130 mL/min/kg in another.[107,199] Infusions in the range used clinically yield plasma dobutamine concentrations from approximately 50 to 190 ng/mL in children and adults.[199] The principal route of elimination is methylation by COMT, followed by hepatic glucuronidation and excretion into urine and bile.[117] 3-O-methyldobutamine also represents a major route of elimination for dobutamine, with up to 33% of the infused drug being eliminated as the sulfoconjugated compound.[204] Dobutamine is also cleared from the plasma by nonneuronal uptake. Some investigators have reported nonlinear elimination kinetics, but other data suggest that dobutamine's kinetics can be adequately described by a simple first-order (linear) model.[105,107,109,199]

Clinical Role

In adults dobutamine produces improvement in a variety of conditions associated with poor myocardial performance, such as cardiomyopathy, atherosclerotic heart disease, and acute myocardial infarction. Dobutamine has been used following surgery for myocardial revascularization, cardiac transplantation, and other procedures associated with postoperative myocardial dysfunction, although undesirable chronotropic effects have been recorded when it has been used after cardiac surgery.[205] It is not clear that septic shock is an appropriate context in which to use dobutamine, unless the primary disturbance is complicated by myocardial dysfunction. Although impaired myocardial performance can be demonstrated early

in patients with septic shock, the main problem relates to regulation of vascular tone, and preferred agents are those that increase systemic vascular resistance. When ventricular dysfunction complicates clinical management, dobutamine may be a useful adjunct. In this context, dobutamine alone or in combination with dopamine has produced an increase in cardiac output, LV stroke work, and blood pressure.[65] As indicated in Table 33.4, dobutamine also can be combined with norepinephrine in treating the patient with myocardial dysfunction that is associated with hyperdynamic shock (eg, a child who has received a cardiotoxic agent to treat cancer and in whom septic shock subsequently has developed).

Several studies in infants and children demonstrate that dobutamine improves myocardial function in a variety of settings.[105,198,199] Stroke volume and cardiac index improve without a substantial increase in cardiac rate. SVR and PVR may decrease toward normal.[203] Dobutamine has been evaluated in children following cardiac surgery with cardiopulmonary bypass. In a study by Bohn and colleagues,[66] dobutamine enhanced cardiac output by increasing heart rate; indeed, tachycardia prompted discontinuation of the infusion in several patients. The expected fall in SVR was not observed in children who received the drug after cardiopulmonary bypass. The authors found no benefit compared with isoproterenol or dopamine. These differences between adults and children may be due to the fact that myocardial dysfunction and CHF are not characteristic of the circulatory status of many children undergoing repair of congenital heart disease. Unlike in adults, the indication for surgery involves abnormalities in cardiac architecture or circulatory anatomy. Berner and associates[206] found that children undergoing operations for mitral valve disease responded to dobutamine with an increase in stroke volume, whereas children with tetralogy of Fallot repair did not, and their cardiac output increased only through a higher heart rate. A more recent report by the same group indicated that following repair of tetralogy of Fallot, dobutamine did enhance cardiac output when it was combined with atrial pacing to increase heart rate. Isoproterenol without pacing provided a higher cardiac output than either dobutamine alone or dobutamine in combination with pacing.[207] Booker and colleagues[208] found that dobutamine and dopamine had equivalent inotropic effects in children following cardiac surgery. Specific indications for dobutamine in the pediatric age group include low output CHF and a normal to moderately decreased blood pressure (see Table 33.4). Typical examples include viral myocarditis; cardiomyopathy associated with use of anthracyclines, cyclophosphamide, or hemochromatosis (related to hypertransfusion therapy); or myocardial infarction (Kawasaki disease).

Dobutamine is *not* a first-line agent to treat low output states that are caused by intracardiac shunt or abnormal cardiac chamber structure. Although dobutamine is used following corrective or palliative cardiovascular surgery in the child, in the context of demonstrated or suspected myocardial dysfunction, milrinone is now considered by many to be the preferred agent for providing inotropy and afterload reduction, despite insufficient evidence of superior effectiveness in a recent meta-analysis.[209] Dobutamine may be of adjunctive value in treating myocardial dysfunction that complicates a primary condition such as ARDS or septic shock. Dobutamine is rarely used as the sole agent to treat compromised hemodynamics associated with sepsis, ARDS, or shock following a severe hypoxic-ischemic event.

Adverse Effects

Dobutamine usually increases myocardial oxygen demand. In subjects with myocardial dysfunction, coronary blood flow and oxygen supply improve with the increase in demand. However, if dobutamine is used when myocardial contractility is normal, oxygen balance will be adversely affected.[210] Tachycardia greatly increases oxygen use by the heart and should prompt a reduction in the dosage of dobutamine (or use of an alternate agent).

Although dobutamine is less likely than other catecholamines to induce serious atrial and ventricular dysrhythmias, these may occur, particularly in the context of myocarditis, electrolyte imbalance, or high infusion rates.[211] Dobutamine and other inotropes should be administered cautiously to patients with dynamic LV outflow obstruction (hypertrophic aortic stenosis). Prolonged infusion of dobutamine inhibits the second wave of adenosine diphosphate–induced platelet aggregation; in a few adult patients petechial bleeding attributed to dobutamine has developed.[212]

Preparation and Administration

Dobutamine is available as a premixed solution in a variety of concentrations. For information regarding compatibility, refer to Table 33.3. Therapeutic dosing ranges between 2.5 and 20 μg/kg/min. Consideration should be given to selecting an alternative agent (epinephrine) if the desired clinical effect cannot be achieved at a dose of 20 μg/kg/min.

Adverse Effects

Adverse cardiovascular effects may include hypertension, tachycardia, and ectopic heart beats. Dobutamine may also cause headache, nausea, vomiting, paresthesia, and dyspnea. Dobutamine may also decrease serum potassium concentrations.

Interactions

The concomitant use of a β-adrenergic antagonist such as propranolol may antagonize the cardiovascular actions of dobutamine.[213] Halogenated anesthetic agents such as halothane may potentiate the adverse cardiovascular effects of dobutamine. Dobutamine may increase the insulin requirement of diabetic patients.

Summary

Dobutamine is a positive inotropic agent that should be reserved to treat poor myocardial contractility. Following cardiac surgery, dobutamine may be used when contractility is abnormal. For septic shock and other acute hemodynamic disturbances, dobutamine is an adjunct when the primary problem is complicated by poor myocardial function (see Table 33.4). In this context, concomitant use of a vasopressor such as norepinephrine may be appropriate.

Vasopressin

Basic Pharmacology

Vasopressin is a highly conserved hormone, and vasopressin-like peptides are present in numerous species. Its main function is to preserve fluid balance in the

organism. In humans, it is released in response to two main stimuli: increases in plasma osmolality and decreases in effective circulating volume or blood pressure. Although vasopressin has long been used for the treatment of diabetes insipidus, its name derives from its vasopressor effect. Vasopressin has a number of effects beyond volume regulation. It acts as a neurotransmitter in the CNS, has a role regulating adrenocorticotropin hormone release, and is involved in thermoregulation, platelet aggregation, and smooth muscle contraction in the uterus and gastrointestinal tract.[31,32]

Clinical Pharmacology

As noted previously, the response patterns are different for the two stimuli for vasopressin release. An increase in plasma osmolality above 280 mOsm/kg leads to a dramatic increase in the release of vasopressin from the posterior pituitary, and the hormone exerts its effect by increasing water reabsorption in the renal collecting duct. The dose/response curve is so steep that when osmolality is 290 mOsm/kg, vasopressin levels exceed those that produce maximal urinary concentration. In contrast, the threshold for release in response to hypovolemia or hypotension is much higher, with decreases of greater than 20% required. However, once the threshold is reached, plasma levels rise 20- to 30-fold (far exceeding levels seen with hyperosmolality).[32] Vasopressin exerts its hemodynamic effects via the V_{1a} receptor, which is coupled to G_q. In the peripheral vasculature, intracellular calcium is increased, enhancing contraction and restoring systemic vascular tone. Vasopressin also inhibits potassium channels, further increasing intracellular calcium.[44,214] Baroreceptors in the left atrium, left ventricle, and pulmonary veins sense changes in volume while baroreceptors in the carotid sinus and aorta sense changes in arterial pressure.[32] Decreased pressure leads to a reduced rate of firing and release of the tonic inhibition of vasopressin release.[31]

Vasopressin is a potent vasoconstrictor when present in the plasma at high concentrations. At the lower concentrations associated with the vasopressin response to hyperosmolarity, it actually induces vasodilation in the pulmonary, renal, and cerebral circulation via the V_2 receptor or oxytocin-mediated nitric oxide release.[215] It does not elevate blood pressure because an associated decrease in heart rate offsets the increase in systemic vascular resistance. For this reason, vasopressin was not originally considered to be a clinically useful agent to treat hypotension.[216] Landry and colleagues[217] measured plasma vasopressin levels in 19 patients with septic shock and 12 patients with cardiogenic shock (all receiving catecholamine support). Surprisingly, plasma levels of vasopressin were not elevated in patients with septic shock (mean 3.1 pg/mL; normal <5 pg/mL). Patients with cardiogenic shock had an expected mean level of 22.7 pg/mL. Vasopressin infusion (0.04 units/min intravenously) in 10 patients with septic shock who were receiving catecholamines produced an increase in systemic vascular resistance and mean arterial pressure, which was associated with a decrease in cardiac index. The resulting plasma level of vasopressin was 30 pg/mL, an appropriate concentration considering the level of hypotension. Therefore vasopressin plasma levels are inappropriately low in patients with vasodilatory septic shock, possibly because of impaired baroreflex-mediated secretion. The authors hypothesized that this phenomenon contributes to the hypotension of vasodilatory septic shock.

It appears that in the early stages of septic shock, vasopressin levels are higher than normal but decrease to either low levels or levels that represent a relative deficiency (normal level in the setting of hypotension) as shock continues.[218] This pattern has also been demonstrated in a model of hemorrhagic shock.[219] In this study, neurohypophysis stores of vasopressin were depleted. In three patients with septic shock and low levels of vasopressin, the high intensity signal from the posterior pituitary on T1-weighted magnetic resonance imaging was lost, suggesting depletion of vasopressin.[218] Hence vasopressin deficiency may occur early in vasodilatory shock and contribute to its pathogenesis.

Pharmacokinetics

Vasopressin circulates as a free peptide and does not exhibit any protein binding.[37] It is degraded rapidly in the kidneys and liver, with 5% to 15% of an IV dose eliminated unchanged in the urine.[138] Renal failure or hepatic insufficiency can prolong the elimination half-life.[220,221] The normal elimination half-life is 10 to 20 minutes.[138]

Clinical Role

The original report by Landry and colleagues[217] generated intense investigation into the clinical applications of vasopressin in the setting of vasodilatory shock. The same group prospectively evaluated vasopressin in patients with vasodilatory shock after placement of an LV assist device.[222] At a dose of 0.1 units/min, vasopressin increased mean arterial pressure and SVR but not cardiac index. Among patients with a high level of endogenous vasopressin, the increase in blood pressure tended to be less. A rapid response to vasopressin was noted in all patients, allowing for the dose to be decreased to as low as 0.01 units/min. This group also published experience with vasopressin in patients with septic shock and children after cardiac surgery.[223,224] In five patients with septic shock, vasopressin was given at doses ranging from 0.03 to 0.05 units/min. Again, blood pressure and SVR increased, allowing for discontinuation of catecholamine support in four patients. Vasopressin was used to treat 11 children with hypotension, on epinephrine infusions following cardiac surgery. At vasopressin doses ranging from 0.0003 to 0.002 units/kg/min, blood pressure increased within 1 hour, and the epinephrine infusion could be decreased in five of eight patients. Two patients who had echocardiographic evidence of poor function died. The remaining nine patients with vasodilatory shock survived and were discharged from the ICU. The authors cautioned against the use of vasopressin in patients with cardiogenic shock, in view of the potential effect on cardiac index. Vasopressin levels were measured in three patients, two of whom had an absolute deficiency and one had a relative deficiency. In adults, vasopressin deficiency (relative or absolute) was associated with shock following cardiopulmonary bypass. Hemodynamic function improved with vasopressin, and the need for other vasopressors decreased.[225] In a small double-blind randomized study, prophylactic vasopressin (0.03 units/minute) decreased the need for norepinephrine and decreased ICU length of stay in patients receiving angiotensin-converting enzyme inhibitors who underwent cardiopulmonary bypass.[226] In another small study (n = 10), patients admitted to a trauma unit with the diagnosis of septic shock were randomly assigned to placebo or vasopressin at 0.04 units/min if they remained in

shock with catecholamine support.[227] In the treatment group ($n = 5$), systolic blood pressure and SVR increased. Other vasopressors were discontinued within 24 hours in patients receiving vasopressin; in only one patient in the placebo group was other vasopressor support discontinued. In a larger, prospective, randomized study, the combination of vasopressin and norepinephrine was evaluated versus norepinephrine alone in patients with catecholamine-resistant vasodilatory shock.[228] Vasopressin was given at a dose of 0.06 units/min. The patients in the vasopressin-norepinephrine arm had a lower heart rate and higher blood pressure, SVR, and cardiac index. They also had reduced requirements for norepinephrine; additionally, the norepinephrine group had a higher rate of new-onset dysrhythmias. Gastric perfusion was also better preserved in the vasopressin group.

In summary, in several studies of patients with vasodilatory shock, vasopressin has been shown to improve blood pressure, increase SVR, lessen the need for catecholamines, improve markers of myocardial ischemia, and improve urine output.[71,229-231] Published experience in pediatric patients with septic shock is still limited. Liedel and colleagues[232] published their experience with five patients, ranging in age from 2 weeks (a 23-week premature infant) to 14 years. Doses used were between 0.0006 units/kg/min and 0.008 units/kg/min (one patient was given 0.06 units/min). In four patients, blood pressure increased and catecholamine support could be decreased. In three patients, urine output improved. Few formal randomized trials of vasopressin in pediatric patients with septic shock or following cardiac surgery have been published to date. In a multicenter, randomized trial involving 69 pediatric patients with vasodilatory shock,[233] vasopressin (0.0005–0.002 units/kg/min) or placebo was added to open-label vasoactive agents. There was no difference in the primary end point of time to vasoactive-free hemodynamic stability (49.7 vs. 47.1 hours) or in any of the secondary outcomes, which included mortality, ventilator-free days, length of critical care unit stay, and adverse events. Ten deaths occurred in the vasopressin group and five in the placebo group (no statistical significance). It was concluded that low-dose vasopressin did not demonstrate any beneficial effects. Vasopressin also has been used as a vasopressor in children undergoing evaluation for brain death.[234] At a dose of 0.04 units/kg/h, blood pressure increased and α agonist support was decreased. No deleterious effect on organ function was noted.

Prior to the most recent (2015) guidelines, vasopressin was part of the Advanced Cardiac Life Support protocol for ventricular fibrillation in adults.[115] For children who experience cardiac arrest, the guidelines state that based on inconsistent results in adult patients, there is insufficient evidence to make a recommendation either for or against the use of vasopressin.[235] Mann and colleagues[236] published their experience with vasopressin during cardiopulmonary resuscitation in pediatric patients in a retrospective case series. In six events involving four patients, vasopressin was given at a dose of 0.4 units/kg after conventional therapy had failed to achieve restoration of spontaneous circulation (ROSC). In all six events, pulseless electrical activity was the initial rhythm, while at the time vasopressin was given, events were asystole, pulseless ventricular tachycardia, and ventricular fibrillation. In four cases, ROSC was achieved for more than 60 minutes. One patient survived to discharge and was in a condition close to her neurologic baseline. A review of the American Heart Association National Registry of Cardiopulmonary Resuscitation in children suggested a lower rate of ROSC and longer arrest duration in patients to

whom vasopressin was administered during in-hospital resuscitation.[237] The authors emphasize that this result should be interpreted with caution, however, because vasopressin was only administered in 64 (5%) of the 1293 cases reviewed, and all of these patients had longer arrest times and were also pretreated with epinephrine.

Dosing and Administration

No standards for pediatric dosing currently exist. The American Heart Association guidelines for pediatric advanced life support[235] suggest a bolus dose of 0.5 units/kg. Standard dosing for vasopressin in vasodilatory shock has not been determined, but the dose used in a recent pediatric study ranged from 0.0005 units to 0.002 units/kg/min.[233] Current guidelines for management of severe sepsis and septic shock in adults suggest vasopressin (0.03 units/min) may be added to norepinephrine to raise mean arterial pressure to target or decrease norepinephrine dose, but that it should not be used as the initial vasopressor.[114]

Adverse Effects

Few adverse events have been reported with the use of vasopressin in the setting of vasodilatory shock. Elevation of liver enzymes and total bilirubin with a decrease in platelet count has been noted, and one series in adults noted six cardiac arrests among 50 patients receiving vasopressin for hemodynamic support.[230,238] All six patients had “severe refractory shock,” and five were receiving a vasopressin dose greater than 0.05 units/min. In 30% of patients receiving vasopressin, ischemic skin lesions of the distal limbs, trunk, or tongue were noted. Preexisting peripheral arterial occlusive disease and the presence of septic shock were identified as risk factors.[238] Extravasation of vasopressin from a peripheral IV catheter was associated with skin necrosis.[239] Treatment with vasopressin at doses used to augment blood pressures and improve hemodynamics may cause hyponatremia, which, in most cases, resolves with discontinuation of the drug.[213] Yet in a case series involving 10 neonates with severe persistent pulmonary hypertension of the newborn who were treated with vasopressin, 0.0002 units/kg/minute, in addition to nitric oxide, no significant decrease in serum sodium was observed.[240] The effect on sodium levels may be a function of patient selection, dose, and duration of treatment.

Interactions

The antidiuretic effect of vasopressin may be antagonized with concomitant administration of epinephrine, heparin, lithium, or demeclocycline.[138] Tricyclic agents, chlorpropamide, carbamazepine, clofibrate, phenformin, and fludrocortisone may exert additive antidiuretic effects when used in combination with vasopressin. Concomitant use of vasopressin with a ganglionic blocking agent can enhance the vasopressor effect of vasopressin.

Summary

Vasopressin has been added to the pediatric ICU practitioner's armamentarium for the treatment of decreased systemic vascular resistance. Its use may elevate blood pressure and urine output in patients with catecholamine refractory vasodilatory shock. Vasopressin should not be used in settings where impaired myocardial function is the principal problem. The optimal dose has yet to be determined, and

the pharmacokinetics of the drug in conditions such as septic shock or after cardiopulmonary bypass need to be further investigated. It may have a more defined role in the future in pediatric advanced life support, but thus far, there is insufficient evidence to make a recommendation for or against the routine use of vasopressin during cardiopulmonary resuscitation from cardiac arrest.

Terlipressin

Basic Pharmacology

Terlipressin (*N*-*α*-triglycyl-8-lysine vasopressin) is a synthetic analogue of mammalian lysine vasopressin, while arginine vasopressin is endogenous to humans.[241] Following IV administration, the three glycyl groups on terlipressin are enzymatically cleaved by endopeptidases, resulting in prolonged release of the active lysine vasopressin moiety. This allows for a longer duration of vasoconstrictive action (4–6 hours) than that of arginine vasopressin (6–20 minutes)[241,242] and obviates the need for administration as a continuous infusion. The vasoactive effects of terlipressin are due in part to direct effects of the parent drug and are not solely a function of the liberated lysine vasopressin moiety.[243,244]

Clinical Pharmacology and Adverse Effects

Clinical trials in adults with refractory septic shock have demonstrated terlipressin to be a potent vasoconstrictor when administered as an IV bolus, with significant increases in SVR, mean arterial pressure, PVR, and urine output, along with reductions in catecholamine requirements and blood lactate levels.[242,245-247] However, adverse effects on myocardial function, including significant reductions in cardiac index, heart rate, oxygen delivery, and oxygen consumption have been observed, raising concerns about the drug's safety profile.

A limited number of trials in children with refractory septic shock suggest a similar pharmacodynamic profile as that observed in adults.[248-251] One retrospective study involving 14 children with septic shock refractory to fluids and vasopressors evaluated the addition of terlipressin IV boluses at an initial dose of 7 μg/kg twice daily, titrated up every 6 hours to a maximum dose of 20 μg/kg, based on blood pressure response.[249] Terlipressin was associated with significant increases in MAP (54 ± 3 to 72 ± 5 mm Hg; $P = .001$) at 10 minutes, and urine output (1.6 ± 0.5 to 4.3 ± 1.2 mL/kg/h; $P = .011$) at 1 hour after administration. A significant reduction in heart rate (153 ± 6.5 to 138 ± 7.5 beats/min; $P = .003$) at 12 hours was also noted. Terlipressin has also been used as a rescue medication in the setting of prolonged pediatric cardiopulmonary resuscitation.[252] In a study of eight episodes of cardiac arrest, terlipressin was administered to 7 infants and children aged 2 months to 6 years, with asystole, who failed to respond to conventional resuscitative measures. Return of spontaneous circulation was achieved in six of the eight episodes, with four patients surviving to discharge from the hospital.

Terlipressin is not currently licensed for use in the United States, and as of this writing, approval is not imminent.

Bipyridines

Inamrinone (formerly known as amrinone), milrinone, enoximone, and piroximone

are nonsympathomimetic inotropic agents. The structure of milrinone, a noncatecholamine inotrope, is shown in Fig. 33.11. Inamrinone, the earliest formulation to be introduced, was associated with an increased risk of thrombocytopenia in both adults and children[253,254] and potentially fatal hypotension,[255] and it is no longer available in the United States. Neither of these complications has been observed with milrinone, which has become the bipyridine of choice.

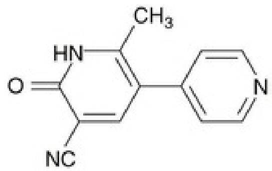

FIG. 33.11 Structure of milrinone.

The pharmacologic effects of the bipyridines result from selective inhibition of phosphodiesterase III and not from interaction with adrenergic receptors or inhibition of sodium-potassium ATPase.[53] These agents produce positive inotropic and lusitropic effects on isolated ventricular tissue, as well as relaxation of vascular smooth muscle. They are often used to improve myocardial contractility and decrease ventricular afterload.

Milrinone

Clinical Pharmacology

A derivative of inamrinone, milrinone shares the same mechanism of action and pharmacodynamic profile. In both adults and children, milrinone acts as an inotrope and vasodilator, producing a direct reduction in preload and afterload.[53,256] Administration to subjects with CHF results in increased cardiac index and reduced systemic vascular resistance, central venous pressure, and pulmonary capillary occlusion pressure,[257] while heart rate is not affected. Systemic hypertension is also reduced.[55,258,259] Patients experience a greater reduction in left and right heart filling pressures and SVR with milrinone than with dobutamine, even at equivalent contractility dosing.[260] Improvement in global hemodynamic function is associated with a more favorable ratio of myocardial oxygen delivery to consumption.[261] Blood pressure is usually maintained, even in the face of reduced SVR, because of the associated improvement in contractility and stroke volume. Increasing doses of milrinone have been shown to correlate with increasing mixed venous oxygen saturation (SvO_2).[262] Milrinone may improve contractility in patients who fail to respond to catecholamines and may further augment cardiac index in patients being treated with dobutamine. Caution is advised when administering milrinone to patients who are intravascularly volume depleted or in whom improvement in cardiac output does not occur, as hypotension may result.[263]

Animal models suggest that phosphodiesterase inhibitors are direct pulmonary vasodilators, even at doses lower than those that increase cardiac output.[264] Milrinone reduces PVR in children with intracardiac left-to-right shunts and elevated PVR, while in children with normal pulmonary pressure, a decrease in

systemic but not pulmonary vascular resistance is observed.[265] PDE III inhibitors provide effective adjunctive therapy in the child with elevated pulmonary vascular resistance and reduced pulmonary blood flow. Milrinone has been used extensively following cardiac surgery in adults. When given perioperatively, milrinone attenuated decreases in gastric mucosal pH in patients undergoing coronary artery bypass grafting.[266] Splanchnic oxygenation improved and systemic levels of endotoxin and IL-6 were decreased. Although a cell culture study showed a possible increase rather than a decrease in proinflammatory markers in response to milrinone, serum levels of IL-1β and IL-6 in human subjects were decreased following cardiopulmonary bypass.[186,267] The decrease in IL-6 correlated inversely with levels of cAMP.

Several studies have evaluated milrinone in children following surgery for congenital heart disease. In one study, a loading dose of 50 μg/kg followed by a continuous infusion of 0.5 μg/kg/min was associated with mild tachycardia and a slight decrease in systemic blood pressure.[268] Cardiac index, however, increased from 2.1 to approximately 3.1 L/min/m^2, while SVR index and PVR index decreased from approximately 2100 to 1300 and 488 to 360 dyne-sec/cm^5/m^2, respectively. In a double-blind, placebo-controlled trial, high-dose milrinone (75 μg/kg bolus followed by continuous infusion at 0.75 μg/kg/min) was associated with a decreased incidence of low cardiac output syndrome.[90] Length of hospital stay was similar among the treatment groups, but prolonged stay (>15 days) was more common in the placebo arm. Milrinone has been shown to increase cardiac index and decrease systemic vascular resistance after the Fontan procedure.[90]

Milrinone also has been evaluated in children with nonhyperdynamic septic shock (ie, normal to low cardiac index and normal to elevated SVR). In a double-blind crossover study, milrinone increased cardiac index, stroke volume index, and oxygen delivery while decreasing SVR.[269] No differences in blood pressure or PVR were seen when milrinone was given at a dose of 0.5 μg/kg/min as a continuous infusion after a bolus dose of 50 μg/kg.

Pharmacokinetics

Milrinone is approximately 70% bound to plasma proteins, with approximately 85% renal elimination.[270] Hepatic glucuronidation accounts for a minor elimination pathway. In healthy adults, milrinone has an apparent volume of distribution of 0.32 ± 0.08 L/kg, clearance of 6.1 ± 1.3 mL/kg/min, and an elimination half-life of 0.8 ± 0.22 hours.[270] Both renal dysfunction and congestive heart failure affect the elimination profile of milrinone, extending the elimination half-life to approximately 2 hours.[271] In infants and young children undergoing cardiac surgery, the weight-adjusted clearance of milrinone was shown to increase with age, ranging from 2.6 mL/kg/min at age 3 months to 5.6 mL/kg/min at age 22 months.[272] In a separate study in infants and children (ages 1–13 years) following open heart surgery, milrinone clearance was significantly lower in infants than in children (3.8 ± 1 vs. 5.9 ± 2 mL/kg/min, respectively).[273] Importantly, the milrinone clearance values for both infants and children were significantly higher than those reported in adults following cardiac surgery (2 ± 0.7 mL/kg/min).[274] In the pediatric study just described, the plasma concentration versus time data fit a two-compartment model.[273] The apparent volume of distribution by area (Vβ), which reflects the volume of distribution during the terminal elimination phase, was not significantly different between infants and

children (0.9 ± 0.4 vs. 0.7 ± 0.2 L/kg). However, the value reported for infants differed significantly from the value reported in adults following cardiac surgery (0.3 ± 0.1 L/kg).[274] In children with septic shock, the median half-life of milrinone was 1.5 hours.[275] Plasma levels did not correlate with changes in cardiac index or SVR. Milrinone clearance is significantly reduced in patients with acute renal dysfunction. A patient with acute renal failure may have as much as an eightfold increase in the serum level of milrinone when exposed to the same dosing regimen as patients with normal renal function.

Clinical Role

Milrinone augments cardiac contractility following cardiac surgery and improves perfusion in patients with "cold shock." Patients who respond with excessive vasodilation, as compared with inotropic effect, may be started on a low-dose catecholamine infusion to maintain target blood pressures. Milrinone's properties as a pulmonary vasodilator have made it a useful adjunct in the treatment of pulmonary hypertension.[276]

Preparation and Administration

Milrinone lactate is available in single-dose vials and as premixed solutions in 5% dextrose.[277,278] Loading doses may be drawn from a single-dose vial and administered undiluted over 15 minutes. A loading dose of 50 μg/kg is generally used in children.[268,272] For maintenance infusions, milrinone should be diluted with 0.45% or 0.9% sodium chloride or 5% dextrose to a final concentration of ≤200 μg/mL. Maintenance infusion rates are generally initiated at 0.5 μg/kg/min, titrated to clinical response. On the basis of the higher clearance and volume of distribution values previously discussed, Ramamoorthy and colleagues[273] suggested a loading dose of 104 μg/kg and initial maintenance infusion rate and 0.49 μg/kg/min, in infants, and 67 μg/kg and 0.61 μg/kg/min, respectively, in children. In patients not given a loading dose of milrinone, changes in cardiac index and plasma levels of milrinone after 3 hours were similar to those seen in patients who received a loading dose.[279] Milrinone is not compatible with furosemide but is compatible with a large number of drugs used in the pediatric ICU, including dopamine, epinephrine, fentanyl, and vecuronium.[280,281]

Adverse Effects

In a large pediatric study, serial measurements showed no difference in platelet count over time (baseline, 36 hours, 72 hours, and discharge) by treatment arm, and there was no difference in the incidence of thrombocytopenia (platelet count <50,000) during the study infusion (7.4% placebo, 8.8% low dose, and 2.6% high dose).[90] As previously stated, milrinone may cause hypotension in patients whose intravascular volume is not replete and in patients with renal dysfunction in whom drug clearance is reduced. Milrinone has been cited as a risk factor for early postoperative tachyarrhythmias in patients following congenital cardiac surgery. In one single-center prospective observational study of 603 patients following surgery for congenital heart disease, the incidence of early postoperative tachyarrhythmias was 50%.[282] Identified risk factors included age, cardiopulmonary bypass, aortic cross clamp time, and the use of milrinone at the time of admission to the cardiac ICU.

Summary

The bipyridines offer an attractive combination of positive inotropy with decreased systemic vascular resistance. They are useful in the short-term management of the infant and child with myocardial disease. Milrinone has an established role in the management of impaired cardiac contractility following cardiopulmonary bypass; its role in other settings has not been conclusively established by randomized trials.

Levosimendan

Basic Pharmacology

Levosimendan is a novel parenteral agent with inotropic and vasodilator properties that is classified as a calcium sensitizer.[283] Originally developed and marketed for inpatient management of acute decompensated heart failure in adults, it is now used in adults and children in the perioperative cardiac surgery setting, and case reports cite several additional applications. It is the R- (-) enantiomer of simendan and is a pyridazole dinitrate derivative. The chemical structure (-)-(*R*)-([4-(1,4,5,6-tetrahydro-4-methyl-6-oxo-3-pyridazinyl)phenyl]-hydrazono) of propanedinitrile is shown in Fig. 33.12. The half-life of the parent compound is short, but the therapeutic effect is sustained for 7 to 9 days due to the formation of an active metabolite, OR-1896.[283-285] This allows levosimendan to be dosed weekly. No age or gender differences in efficacy or metabolism have been observed, and tolerance to the drug does not occur.[283,286]

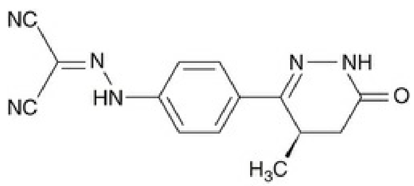

FIG. 33.12 Chemical structure of levosimendan.

Clinical Pharmacology

Classified as a cardioprotective inodilator, levosimendan displays three main clinical features: inotropy, vasodilation, and cardioprotection. It shares many of the functional properties of milrinone. As an inotrope, it acts by binding to calcium-saturated troponin C, stabilizing the calcium-bound conformation of troponin, thereby prolonging the actin-myosin interaction without altering cross-bridge cycling.[287-289] Unlike many inotropes, levosimendan does not increase intracellular calcium and therefore does not substantially increase the risk of arrhythmias or myocardial oxygen demand.[290,291] As with milrinone, phosphodiesterase III inhibition occurs, but at therapeutic doses, it is not the predominant mechanism via which levosimendan exerts its inotropic effects.[286,289]

As a vasodilator, levosimendan works by opening potassium-ATP channels on the sarcolemma of smooth muscle cells.[292,293] Hyperpolarization inhibits calcium channels and promotes sustained vasodilation, thus improving perfusion, in cardiac vessels, lungs, gastric mucosa, and the renal medulla.[294] Levosimendan also increases

coronary blood flow by decreasing coronary vascular resistance[293,295] and through this mechanism may increase myocardial oxygen supply. Finally, levosimendan provides cardioprotection by opening mitochondrial potassium channels on cardiomyocytes.[287] These channels are said to be important mediators of ischemic preconditioning.[287,296] Although this theory has not yet been formally studied, this proposed cardioprotective property has led to the use of levosimendan preoperatively in patients at risk for myocardial ischemia during cardiac surgery on cardiopulmonary bypass.[297,298]

Levosimendan may also act as an antiinflammatory and antiapoptotic agent by decreasing proinflammatory cytokine production and downregulating NF-κ β-dependent transcription.[284,299]

Pharmacokinetics

The pharmacokinetics of levosimendan are linear at therapeutic dosages (0.05–0.2 μ/kg/min).[285] The relatively short half-life of the parent drug (approximately 1 hour) enables rapid onset of action, while the long elimination half-life of 70 to 80 hours of the active metabolite, OR-1896, in patients with heart failure allows for sustained activity.[285] Following IV administration, the majority of levosimendan is reduced via glutathione to inactive metabolites and excreted in the urine as cysteineglycine and cysteine conjugates.[283,285] *N*-acetylated cysteineglycine conjugates are excreted in feces. Small amounts of levosimendan and its metabolites, OR-1855 and OR-1896, are eliminated unchanged in the urine. Approximately 6% of the drug is excreted into the small intestine and reduced by intestinal bacteria to an amino phenolpyridazinone metabolite (OR-1855) and then further metabolized by acetylation to the *N*-acetylated conjugate (OR-1896).[283] The maximal concentration of these two metabolites is observed approximately 48 hours after completing a 24-hour infusion. Small studies in children suggest the pharmacokinetics of levosimendan are similar to those in adults.[300,301] Pharmacokinetics are influenced by albumin levels and intestinal (bacterial) flora, as well as hepatic, renal, and gastrointestinal function.[283]

In patients with renal failure, the half-life of the active metabolites is prolonged 1.5-fold (to 94 to 97 hours) and the peak concentration and area under the concentration curve (AUC) are nearly twice that of patients with normal renal function.[284,302] Therefore caution is advised when treating patients with mild to moderate renal and hepatic dysfunction. Levosimendan is not recommended in patients with severe renal or hepatic failure.[294]

Clinical Role

Levosimendan was developed primarily as a parenteral inodilator for use in hospitalized adults with acute decompensated heart failure. In patients with severely elevated plasma brain natriuretic peptide (BNP), NT-proBNP (the promolecule), and endothelin 1 levels, treatment with levosimendan resulted in significant reductions in all three indicators.[303,304]

Use of levosimendan as a cardioprotective agent in adults and children undergoing cardiac surgery on cardiopulmonary bypass and in adults with heart failure undergoing noncardiac surgery is becoming more commonplace.[298,305,306] In adults with heart failure, when initiated before coronary artery bypass grafting,

levosimendan was shown to prevent myocardial stunning and attenuate postoperative myocardial dysfunction.[298] Results from six phase IIb and phase III trials in Europe, comprising more than 3500 patients, comparing levosimendan with dobutamine in adults with acute decompensated heart failure, have been mixed. In one randomized trial[307] levosimendan demonstrated a significant mortality benefit at 28 days and at 6 months over dobutamine (8% vs. 17%), while results from another trial[308] failed to demonstrate reduced all-cause mortality at 180 days when levosimendan was compared with dobutamine. However, in this trial, levosimendan was superior to dobutamine when comparing morbidity in hospitalized patients. A 2012 meta-analysis by Landoni and colleagues[309] involving 45 studies and more than 5000 adult patients demonstrated a decrease in mortality and length of hospitalization when levosimendan was compared with dobutamine and placebo.

Case reports suggest levosimendan may improve myocardial function in sepsis and septic shock where cardiogenic shock is a major feature.[287,310] In postoperative and heart failure patients with renal dysfunction, levosimendan preserves renal function by improving renal blood flow and glomerular filtration rate through "preglomerular vasodilation."[294,311] The evidence for indications for levosimendan other than heart failure or perioperative cardiac and renal protection is anecdotal and limited to case reports and small, observational studies; large, randomized controlled studies have not been published.[312-314]

Although widely available in Europe for more than a decade, licensing of levosimendan in the United States was denied when the initial application was filed with the FDA in 1998, pending additional safety and efficacy data. Fast-track approval status was recently awarded to levosimendan for use in cardiac surgery patients at risk for low cardiac output syndrome pending results of a large industry-sponsored phase III trial.[298]

Currently, there are no official indications for levosimendan in patients younger than 18 years old, but published reports suggest it has been used as a rescue medication in more than 600 pediatric patients in the operating room and the PICU.[315,316] In one single-center study of 293 pediatric patients with cardiomyopathy or severe cardiac dysfunction following cardiac surgery, levosimendan as compared with milrinone was shown to delay the need for mechanical cardiac support.[316] In a second clinical trial, neonates undergoing cardiac surgery experienced an increase in cardiac index, while the group receiving milrinone demonstrated no change. Patients in the levosimendan group also had higher pH, lower blood glucose, and lower inotrope scores as compared with those on milrinone.[317]

Preparation and Administration

Levosimendan is marketed as a 2.5 mg/mL concentrated solution for IV infusion. The concentrate must be diluted with 5% dextrose solution to yield a final concentration of 0.025–0.05 mg/mL and should be used within 24 hours of preparation.[284] A loading dose of 6–12 μg/kg may be administered over 10 minutes before starting the continuous infusion if immediate effects are needed.[285] The lower bolus dosing should be used for patients who are receiving concurrent inotropic agents. Recommended dosing of the infusion ranges from 0.05–0.2 μg/kg/minute and is limited by the appearance of adverse effects.[307,318] Maximum infusion duration should not exceed 24 hours.[284,287] Caution should be taken in patients with renal and hepatic disease.

Adverse Effects

The most common adverse effects are hypotension, headache, palpitations, dizziness, tachycardia, atrial fibrillation, and hypokalemia.[311,319] Headache and hypotension are the direct result of vasodilation.[290] A clinically insignificant decrease in hemoglobin and erythrocyte counts has also been observed.[319] In adults with systolic blood pressures less than 100 mm Hg and/or diastolic pressures less than 60 mm Hg, use of levosimendan may increase mortality risk.[304]

Interactions

No significant drug interactions have been observed, but caution is advised when using levosimendan with agents that lower blood pressure. Unlike dobutamine (and other agents that employ β-adrenergic pathways), the effects of levosimendan are not attenuated by the coadministration of β-blocking agents.[307,320]

Summary

Levosimendan is a calcium-sensitizing agent with inotropic, vasodilator, and cardioprotective properties indicated for the short-term treatment of decompensated congestive heart failure in hospitalized patients. Although the parent drug has a short half-life, the formation of active metabolites confers a prolonged treatment effect of up to 7 to 8 days, thus allowing for weekly 24-hour infusions.

In addition to its inotropic properties, levosimendan has cardioprotective properties that have proven useful in the perioperative setting in patients at risk for ischemia and low cardiac output syndrome. Heart failure patients undergoing noncardiac surgery have also been pretreated with levosimendan with promising results.[306]

Although used extensively in adults and children in Europe for over a decade, the drug is not yet approved in the United States. There are no official indications for levosimendan in patients younger than 18 years of age.

Nesiritide

This once promising parenteral agent for the management of acute decompensated congestive heart failure is rarely used, due in part to cost, which approaches 40 times that of conventional therapies,[321] but more importantly because of concern over adverse effects. Studies comparing nesiritide with conventional therapy for decompensated heart failure did not find it to be superior, and a large meta-analysis[322,323] suggested a possible increased risk of renal dysfunction and mortality. As a result, the use of nesiritide rapidly declined,[324] and it is now indicated as a rescue medication in patients with life-threatening heart failure who do not respond to conventional therapy (eg, nitroglycerin, nitroprusside, milrinone, diuretics) or those in whom inotropic or chronotropic agents cannot be used due to the presence of arrhythmias.

Digitalis Glycosides

The role of digoxin in the acute care of critically ill children has always been limited by a narrow therapeutic index, slow onset of action, and the potential for life-

threatening adverse effects. With the advent of new therapies for both the acute and chronic management of CHF and myocardial dysfunction, its role has further decreased. The practitioner in the pediatric ICU may still encounter patients receiving the drug, particularly for control of dysrhythmias. As is true for the catecholamines and other drugs discussed in this chapter, digoxin exerts its inotropic effects by increasing intracellular calcium.

Basic Pharmacology

Cardiac glycosides consist of a steroid moiety with one to four sugar molecules attached.[325] The number and composition of the associated sugar molecules affect the pharmacokinetics of the specific glycoside; all digitalis glycosides have similar pharmacodynamic properties. Glycosides bind to and inhibit sodium-potassium ATPase. Binding of digoxin to ATPase is affected by serum potassium. Hyperkalemia depresses digoxin binding, whereas hypokalemia has the opposite effect, accounting in part for potentiation of digoxin-induced dysrhythmias during hypokalemia.[326] As described earlier in this chapter, inhibition of ATPase produces an increase in intracellular calcium and enhances the inotropic state of the myocardium.

Clinical Pharmacology

In patients with CHF, the positive inotropic action of digoxin leads to increased cardiac output and reductions in filling pressures, edema, and sinus node rate. In a study of 10 adult patients with acute myocardial failure, a single dose of 10 μg/kg of digoxin produced a 69% increase in LV stroke work index, a 25% reduction in pulmonary capillary occlusion pressure, a 16% to 28% increase in cardiac index, and a 25% increase in stroke index within 2 hours of infusion.[327] Many of these changes were present within 60 minutes. In infants, digoxin is known to produce changes in echocardiographic measurements that are associated with an improved inotropic state, although detailed invasive hemodynamic measurements have not been made in infants or children.[10,200,327,328] When CHF is due to obstructive lesions or left-to-right shunts, it is more difficult to demonstrate benefit than when CHF is due to myocardial failure.

In patients with CHF who have a sinus rhythm, administration of digoxin produces a decrease in heart rate, likely because of improvement of the inotropic state and withdrawal of compensatory sympathetic activity. In addition, digoxin enhances vagal tone by increasing baroceptor sensitivity and directly stimulating central vagal centers,[326] which leads to direct slowing of heart rate, augmenting that produced by improved function. Another effect of digoxin-mediated enhanced vagal tone is slowed conduction of atrial impulses through the atrioventricular node to the ventricle. This property is exploited in use of digoxin to control or treat supraventricular tachycardia and atrial flutter or fibrillation. This aspect of digitalis pharmacology is reviewed in Chapter 35.

Use of digoxin in the pediatric ICU is further complicated by the large number of pharmacokinetic and pharmacodynamic interactions between digoxin and other pharmacologic agents used in critical care.[329] For example, carvedilol (a β-blocker) has been shown to decrease the elimination of digoxin in children, necessitating a

reduction in digoxin dosage.[330] Toxicity is a major limiting factor in administering digitalis glycosides to critically ill patients. The most frequent side effects are gastrointestinal; the most serious are disturbances in cardiac rhythm.[10,325] Digitalis toxicity is reviewed in several of the references.[331,332] In adults and older children the dominant manifestations of digoxin toxicity are tachydysrhythmias such as ventricular premature contractions, ventricular tachycardia, and ventricular fibrillation. Atrial tachycardia and junctional tachycardia may also occur. Bradycardia and A-V conduction block are seen with acute, profound intoxication and in infants with enhanced vagal tone and diminished sympathetic activity, where the dominant findings are A-V conduction block and sinus bradycardia.

The risk of digitalis toxicity increases with factors that increase myocardial irritability, such as myocarditis, ischemia, hypoxemia, or catecholamine support. Hypokalemia and alkalosis also potentiate digoxin-induced dysrhythmias. Treatment of digoxin toxicity involves supportive treatment and correction of electrolyte disturbances.[333] Specific pharmacologic support (eg, with atropine, lidocaine, phenytoin, or magnesium sulfate) may be necessary (although frequently unsuccessful), and in life-threatening circumstances, treatment with digoxin-specific Fab antibody fragments is indicated.[334]

Pharmacokinetics

The dosage of digoxin prescribed for young children and infants is much higher than that applied to older children and adults. In the past, this disparity was ascribed to the incorrect belief that developmental immaturity was associated with decreased myocardial sensitivity to digitalis. It is now understood that neonates are not less sensitive to digoxin but eliminate digoxin more rapidly.[10] Clearance is dependent on age, although there is wide interindividual variation during the first year of life.[329] Thus infants may require higher loading (“digitalizing”) and maintenance dosages to achieve therapeutically effective plasma concentrations of 1–2 ng/mL. Distribution of digoxin is relatively slow; therefore plasma levels will be misleadingly elevated if determined sooner than 6 hours following administration of a dose. At distribution equilibrium, the concentration of digoxin in the heart is 15 to 30 times greater than that in the plasma. In the nonacutely ill child, the half-life of digoxin is 36 hours with a clearance of 8.6 L/h.[40] Digoxin is eliminated through glomerular filtration and renal tubular secretion mechanisms, including the efflux pump, P-glycoprotein (P-gp). A polymorphism that decreases the activity of this enzyme was associated with increased serum digoxin levels.[335] Elimination is also strongly affected by renal dysfunction, complicating use of the agent in the critically ill child.

Clinical Role

The role of digoxin in the care of the pediatric patient continues to be refined and narrowed. Its role as an inotropic agent in the acute setting has been supplanted by other drugs (eg, milrinone) with a more favorable pharmacodynamic profile. Use of digoxin to improve cardiac function in children with systemic to pulmonary shunts has also decreased greatly, and it is used primarily now to control dysrhythmias and improve systolic function in children without structural lesions.[332] Because digoxin does not produce β-adrenergic receptor desensitization and has beneficial effects by

virtue of decreased sympathetic activity, it continues to have a clinical role in the outpatient management of pediatric congestive heart failure.

Preparation and Administration

Digoxin is available in both parenteral and oral formulations. It may be administered undiluted, or it may be diluted with sterile water for injection, D5W, or 0.9% sodium chloride for injection. The injectable form must be diluted at least fourfold to avoid precipitation.

Adverse Effects

Cardiovascular adverse effects may include sinus bradycardia, atrioventricular block, ventricular tachycardia, and other dysrrhythmias.[329] Gastrointestinal adverse effects of digoxin include nausea, vomiting, anorexia, diarrhea, constipation, abdominal pain, and abdominal distension. Other effects may include visual disturbances, photophobia, headache, muscle weakness, fatigue, drowsiness, dizziness, vertigo, seizures, and neuropsychiatric abnormalities.

Interactions

The adverse cardiovascular effects of digoxin may be potentiated by agents that lower serum potassium or magnesium concentrations, such as thiazide diuretics, loop diuretics, ethacrynic acid, amphotericin B, corticosteroids, polystyrene sodium sulfonate, and glucagon.[329] The concomitant administration of digoxin with IV calcium results in additive or synergistic inotropic and adverse cardiovascular effects. β-adrenergic antagonists can cause complete heart block when administered with digoxin. Using digoxin with succinylcholine or sympathomimetics increases the risk of dysrhythmias. Digoxin has a narrow therapeutic index; serum digoxin concentrations are increased with concomitant administration of amiodarone, flecainide, quinidine, propafenone, verapamil, captopril, itraconazole, and indomethacin.

Summary

Digitalis glycosides are inotropic agents that have the added benefit of slowing rather than accelerating heart rate. Given its narrow therapeutic window, long half-life, and with the emergence of newer medications, there is rarely a role for digoxin in the acute setting.

Conclusion

Significant advances have been made in our understanding of the mechanisms underlying adrenergic receptor signaling, the control of vascular tone, and the influence of genetic polymorphisms on the pathways involved in these processes. Despite this broader fund of knowledge, the therapeutic options for supporting the patient with impaired end-organ perfusion remain essentially unchanged. The catecholamines comprise the mainstay of therapy for patients in need of inotropic or vasopressor support. Although dopamine is still used, epinephrine and

norepinephrine are increasingly becoming the mainstay of therapy for patients with poor cardiac performance or decreased systemic vascular tone, respectively.

Milrinone, levosimendan, or dobutamine can be used to increase myocardial contractility in the absence of hypotension. Milrinone is particularly useful for hemodynamic support after surgery for congenital heart disease. Vasopressin has emerged as an option for vasodilatory shock that is resistant to catecholamine therapy. Often the clinical picture is mixed, and the patient may require both inotropic and vasopressor support. Careful attention to hemodynamics and end-organ perfusion, as well as a thorough understanding of cardiovascular pharmacology, is necessary in order to select the agent(s) that will provide the optimal results in critically ill patients.

CHAPTER 34

Cardiopulmonary Interactions

Bradley P. Fuhrman, Ronald A. Bronicki

PEARLS

- Positive pressure ventilation (PPV) alters ventricular loading conditions and compliance.
- In patients who are hypovolemic, the effects of positive airway pressure on the right heart predominate, whereas in patients who have systemic ventricular systolic dysfunction, the effects of PPV on left ventricular afterload predominate.
- Large changes in arterial pulse pressure over the respiratory cycle help to identify mechanically ventilated patients who will have a favorable response to the administration of fluid or who may not tolerate high levels of positive end-expiratory pressure without fluid administration.
- PPV raises juxtacardiac pressure, thereby reducing left ventricular afterload.
- Respiratory effort imposes critical loads on the heart, and respiratory muscle failure from inadequate oxygen delivery is a final common pathway to death from shock.

Both spontaneous breathing and positive pressure ventilation (PPV) affect the circulation in predictable ways. The cardiovascular system also has important effects on respiration, ventilation, and gas exchange.

Effects of Ventilation on Circulation

As shown by Cournand[1] in his sentinel paper, PPV can have important effects on the circulation. The magnitude of these effects may be accentuated by factors that compromise cardiovascular homeostatic responsiveness, such as hypovolemia, cardiac dysfunction, or disordered vascular tone.

PPV alters ventricular loading conditions and compliance. These interactions may occur simultaneously and yet not act in the same direction on cardiac output. The net effect on cardiac output depends on which interactions predominate over the

course of the respiratory cycle and on underlying cardiopulmonary function. For this reason, it is often easier to rationalize an interaction than to predict it.

For clarity of discussion, wherever the terms *positive pressure* or *mechanical ventilation* are used in this chapter, the patient is presumed to respond passively, as though subjected to neuromuscular blockade. In general, the term *preload dependence* is used in this chapter to connote patients in whom the dominant cardiovascular effect of positive pressure breathing is to reduce right heart filling with resultant fall in stroke volume. *Afterload dependence* is the term applied to identify patients whose dominant effect is afterload reduction and consequent increase in stroke volume.

Right Ventricular Filling and Stroke Volume

The effects of PPV on filling of the right heart are the best understood of the various heart-lung interactions, are generally the preponderant effects on the circulation, and are mediated by changes in intrathoracic pressure and venous return over the respiratory cycle. Spontaneous breathing and PPV have opposite effects on intrathoracic pressure, which largely explains their different effects on cardiac output.

Venous Return

The mean systemic pressure of the circulation (P_{ms}) is thought to be the inflow pressure driving blood toward the right atrium.[2] This driving pressure is not measurable in the intact patient, but it can be thought of as the static mean pressure that might exist throughout the circulation if there were instantaneously no blood flow.[3] P_{ms} approximates the weighted average of pressures in venous reservoirs throughout the body during the circulation of blood.[4] The back pressure that opposes systemic venous return is the right atrial pressure (P_{ra}). The impact of these pressures on the return of venous blood to the heart is described by the venous return curve (Fig. 34.1A), which is drawn in such a way that the independent variable (Qpump) appears on the y-axis. Picture the systemic circulation as composed of noncompliant arteries functioning largely as conductive vessels and venous reservoirs functioning as capacitive vessels, which are separated by high-resistance arterioles and a pump that receives venous return and propels it into the systemic arterial circulation (Fig. 34.1B). The faster the pump circulates the blood, the more blood piles up before the arterioles and the higher the arterial pressure will be, and the faster the pump moves blood from venous to arterial system, the less blood resides on the venous side of the circuit and the lower the right atrial pressure will be (x-axis). As the pump is slowed down, venous pressure rises until flow reaches zero, at which point vascular pressures equilibrate throughout the circulation at P_{ms}. Resistance to venous return (R_{vr}) is the reciprocal of the slope of the linear part of the venous return curve.

$$\text{Simply stated: Venous Return} = (P_{ms} - P_{ra})/R_{vr} \qquad \textbf{Eq. 34.1}$$

P_{ms} is a function of intravascular volume and compliance, the vast majority of which reside within and with the venous reservoirs. The P_{ms} can be altered by

changes in venous tone and intravascular volume. P_{ms} is an extrathoracic measurement and is less sensitive than P_{ra} to changes in intrathoracic pressure.[5] P_{ra}, in contrast, is quite sensitive to changes in intrathoracic pressure.

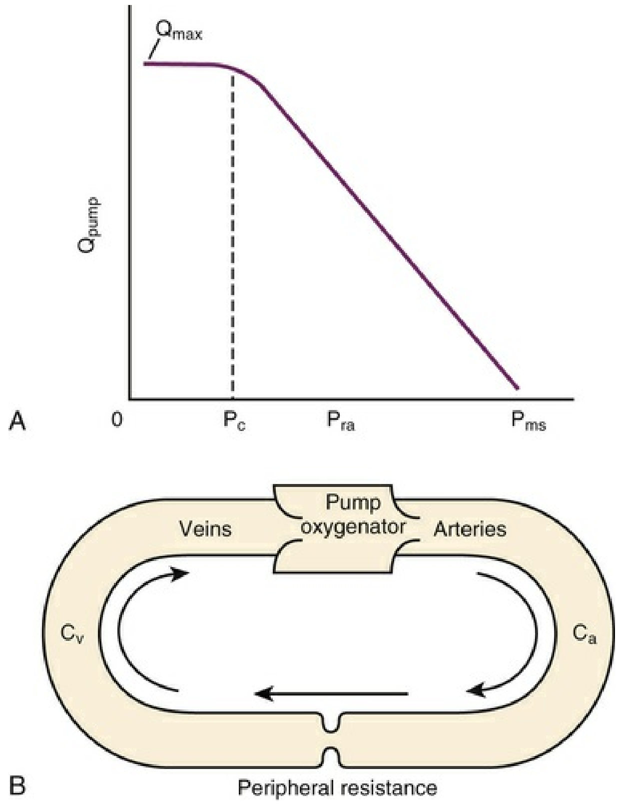

FIG. 34.1 (A) Systemic venous return curve. Flow *(Q_{pump})* is plotted on the ordinate but is treated as the independent variable. Right atrial pressure *(P_{ra})*, the dependent variable, is plotted on the abscissa. (B) Circulation is treated as though a pump transferred blood from veins to arteries, generating arterial pressure sufficient to overcome peripheral arterial resistance. Arterial compliance *(C_a)* and venous compliance *(C_v)* determine the volume of blood distending arteries and veins at any Q_{pump}. When there is no flow, pressure equilibrates throughout the circulation at the mean systemic pressure of the circulation P_{ms}. As pump flow is progressively increased, venous pressure falls and arterial pressure rises because of the net transfer of blood from veins to arteries by the pump and because of the accumulation of blood before the peripheral resistance. When venous pressure falls to P_c, the critical closing pressure of the venous system, no further increase in pump flow is possible. (Modified from Guyton AC. Determination of cardiac output by equating venous return curves with cardiac response curves. Physiol Rev. 1955;35:123.)

At functional residual capacity (FRC), the thorax exerts recoil force, tending to spring outward, whereas the lung exerts recoil force (mostly as a result of alveolar surface tension), tending to collapse inward. These forces result in subambient pleural pressure. The cardiac fossa, or juxtacardiac space, which surrounds the pericardium and heart, shares in this balance of forces and has slightly negative pressure at apneic FRC. At any right atrial volume, P_{ra} is influenced by juxtacardiac

pressure because these two forces act together to oppose the right atrium's balloon-like tendency to recoil inward. Therefore it is not surprising that all of these pressures (pleural, juxtacardiac, and right atrial) are influenced by the respiratory cycle.[6-8]

During spontaneous breathing, lung volume rises from FRC to end-inspiratory volume by expansion of the rib cage and descent of the diaphragm. This reshaping of the thorax stretches the lung, increasing its recoil tension, so pleural pressure and juxtacardiac pressure both become more negative (subambient). At any right atrial volume, spontaneous inspiration reduces P_{ra}. By the mathematic relationship in Eq. 1, this augments venous return.[9] Over the course of passive spontaneous expiration, all three pressures return toward their values at FRC. It follows that intrathoracic pressure, during relaxed spontaneous breathing, is always most negative at end-inspiration and becomes progressively less negative throughout the rest of the respiratory cycle.

Right Ventricular Preload and Stroke Volume

Transmural pressure is the pressure difference across (inside to outside) a hollow structure. This pressure difference and the wall tension of the structure determine its resting radius, or, at disequilibrium, its internal pressure. P_{ra} normally approximates the pressure within the right ventricle during cardiac filling, when the tricuspid valve is open. Juxtacardiac pressure approximates the pressure surrounding the ventricle. During spontaneous inspiration, systemic venous return to the right atrium and ventricle are augmented (Eq. 1), end-diastolic right ventricular (RV) volume rises, and right ventricular stroke volume increases by the Frank-Starling mechanism. Despite the falling P_{ra}, transmural pressure is increased by spontaneous inspiration and right ventricular stroke volume increases; hence there is a seemingly paradoxical inverse relationship between P_{ra} and right ventricular stroke volume over the spontaneous respiratory cycle (Fig. 34.2).[10] However, if *transmural* P_{ra} is plotted against right ventricular stroke volume during various respiratory maneuvers and with expansion of intravascular volume, the expected positive relation of RV filling pressure to stroke volume is revealed (Fig. 34.3).[11]

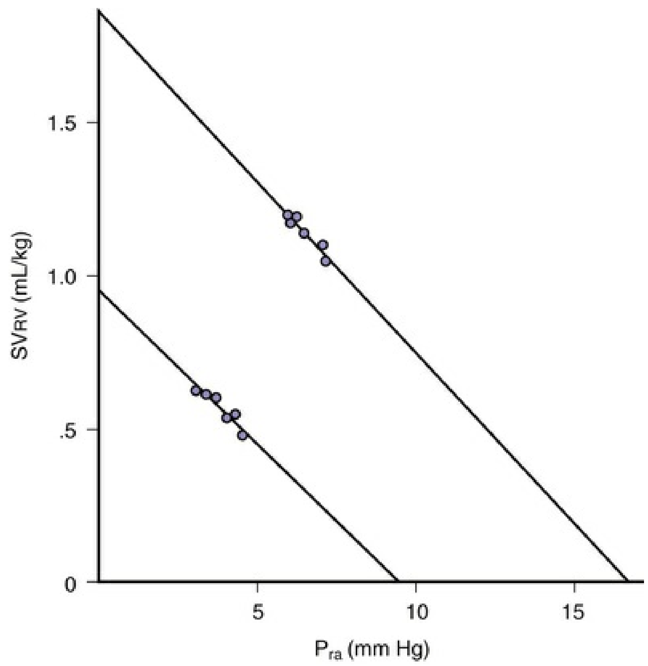

FIG. 34.2 During spontaneous inspiration, right atrial pressure *(P_{ra})* falls, but this decline is associated with an increase in right ventricular stroke volume *(SVRV)*. Shown at two different mean P_{ra}. (From Pinsky MR. Instantaneous venous return curves in an intact canine preparation. J Appl Physiol. 1984;56:765.)

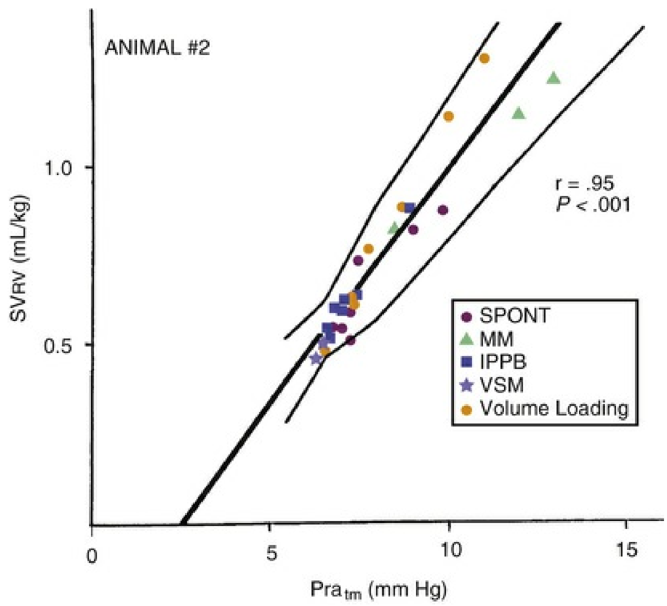

FIG. 34.3 Over a wide range of respiratory maneuvers, right ventricular stroke volume *(SVRV)* varies directly with transmural right atrial pressure *(Pra_{tm})*. *IPPB,* intermittent positive pressure breathing; *MM,* Müller maneuver; *SPONT,* spontaneous breathing; *VSM,* Valsalva maneuver. (From Pinsky MR. Determinants of pulmonary arterial flow variation during respiration. J Appl Physiol. 1984;56:1237.)

Positive Pressure Mechanical Ventilation and Right Ventricular

Preload

The effects of PPV on pleural, juxtacardiac, and right atrial pressure are opposite those of spontaneous breathing. A common goal in the application of positive end-expiratory pressure (PEEP) is restoration of normal end-expiratory lung volume (normal FRC). All other things being equal, pleural pressure, which opposes thoracic recoil, should be the same at end-expiration whether breathing is spontaneous or mechanical. Pleural pressure is, after all, determined by thoracic volume during passive expiration.

During spontaneous inspiration, active reshaping of the thorax by the respiratory muscles and diaphragm inflates the lungs by reducing pleural pressure. In contrast, throughout positive pressure mechanical inspiration, pleural pressure rises because the passive thorax is pushed outward (from FRC to end-inspiratory volume) by the expanding lungs. Passive expiration restores pleural pressure to that of FRC. Averaged over the entire respiratory cycle, pleural pressure is higher during positive pressure breathing than it would be during spontaneous breathing (Fig. 34.4). (This elevation of pleural pressure during positive pressure mechanical ventilation may be thought of as transmission of airway pressure to the pleural space.) PPV, therefore, reverses the effects of spontaneous breathing on venous return[12] and RV transmural pressure.[13] RV stroke volume declines during positive pressure inspiration as P_{ra} rises. Averaged over the entire respiratory cycle, P_{ra} is raised and RV stroke volume is reduced by positive airway pressure relative to their expected values during spontaneous breathing (Fig. 34.5). It is easy to argue from these observations that PPV will invariably decrease venous return to the right heart, but this is not always the case. In addition to the extent to which airway pressure is transmitted to the right atrium, discussed further later, the adequacy of circulatory reflexes to maintain an adequate albeit elevated P_{ms}, as well as underlying cardiac function, determines the extent to which cardiac output is adversely impacted by PPV. Venoconstriction and retention of intravascular volume act to elevate the P_{ms} and maintain an adequate pressure gradient for systemic venous return. During PPV, descent of the diaphragm may displace blood from the abdominal viscera[14,15] and positive airway pressure may displace blood from the pulmonary circulation, both of which raise P_{ms}.

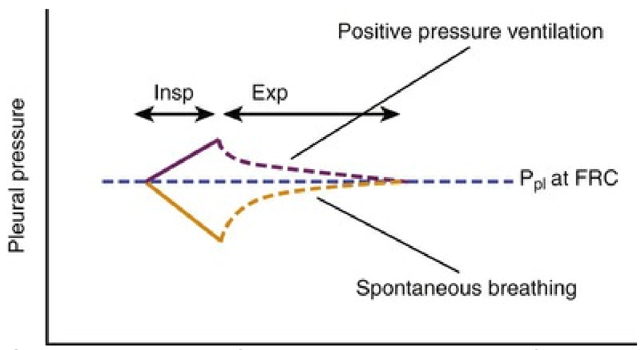

FIG. 34.4 Over the course of the respiratory cycle, if spontaneous and positive pressure breaths both begin and end at the same functional residual capacity *(FRC)*, spontaneous breathing takes place at lower pleural pressure than does positive pressure ventilation.

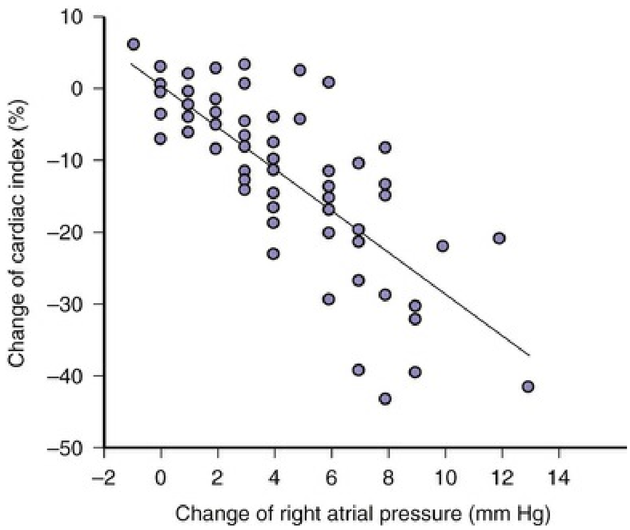

FIG. 34.5 Relationship between the percentage change in cardiac index and the percentage change in right atrial pressure that was produced by the application of graded levels of positive airway pressure in adults. (From Jellinek H, Krafft P, Fitzgerald RD, et al. Right atrial pressure predicts hemodynamic response to apneic positive airway pressure. Crit Care Med. 2000;28:672.)

Critical Illness and the Effects of Positive Pressure Breathing on the Right Heart

Among the effects of critical illness are capillary leak, chest wall edema, pulmonary edema, surfactant dysfunction, abnormal blood volume, and abdominal distension. Each of these modifies the effects of positive pressure breathing on the right heart. Capillary leak alters the compliance of the atrial and ventricular chambers, modifying the responsiveness of the heart to changes in preload. Sepsis and inflammation decrease cardiac contractility, directly altering the way the heart responds to changes in preload. Chest wall edema, pulmonary edema, surfactant dysfunction, and abdominal distension alter thoracic and pulmonary compliances, which in turn alter pleural and juxtacardiac pressures.

Reduced respiratory system compliance diminishes the transmission of alveolar pressure to the juxtacardiac space.[16] The change in intrathoracic pressure that occurs with a change in static airway pressure is essentially the same as the change observed in pulmonary artery wedge pressure,[17] which is readily measured. Recognizing this relationship in adults has made it possible to estimate percent transmission of airway pressure to the juxtacardiac space by measurement of respiratory system compliance (Fig. 34.6).

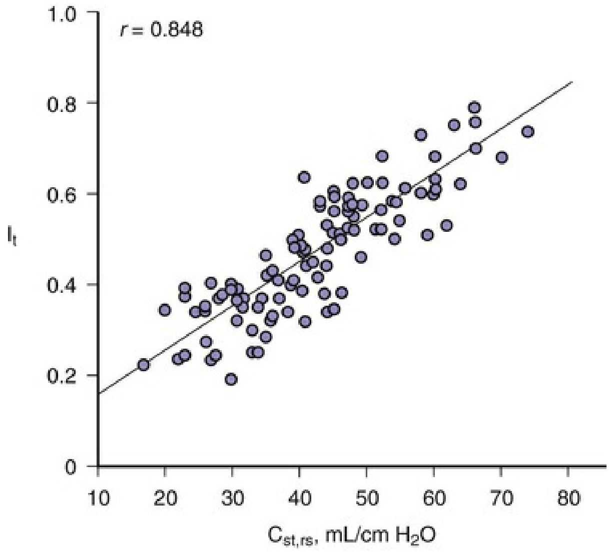

FIG. 34.6 Relationship between the static compliance of the respiratory system (*$C_{st,rs}$*) and the index of transmission (*I_t*, decimal fraction) of a change in static airway pressure to the pulmonary circulation in adults. I_t values for pleural and juxtacardiac spaces are presumed to be comparable. (From Teboul JL, Pinsky MR, Mercat A, et al. Estimating cardiac filling pressure in mechanically vented patients with hyperinflation. Crit Care Med. 2000;28:3631.)

Both abnormal blood volume and abnormal vascular compliance can change P_{ms} and thereby alter venous return. Vascular hypovolemia can exaggerate the adverse effects of PPV on preload, and hypervolemia can blunt that effect.

Pulmonary Circulation

By modifying pulmonary vascular resistance (PVR), the effects of breathing on pulmonary circulation modify RV afterload. The effects of breathing also can change the distribution of pulmonary blood flow within the lung. Both effects are significant.

Lung Volume

The alveolar septae are highly vascular (Fig. 34.7). More than 90% of the alveolar surface makes contact with alveolar capillaries. These vessels can be separated into two categories according to their location or response to lung inflation. Most alveolar vessels are capillaries and lie in septa, which separate adjacent alveoli. Other alveolar vessels are termed *corner vessels* because they are located at the intersection of alveolar septae. These corner vessels are generally larger and most likely will divide later in their course to become alveolar capillaries located in septa between adjacent alveoli. When the lung is stretched by either spontaneous inspiration or positive pressure distension, corner vessels are pulled open by radial traction and their resistance to blood flow is reduced. When alveolar septae are stretched, alveolar capillaries are stretched, become thinner, and restrict flow. Moreover, lung distension by positive airway pressure compresses alveolar capillaries. The net effect of these factors is a U-shaped relation of PVR to lung volume (Fig. 34.8)[18-21]; PVR is least at FRC and rises with either atelectasis or overdistension.

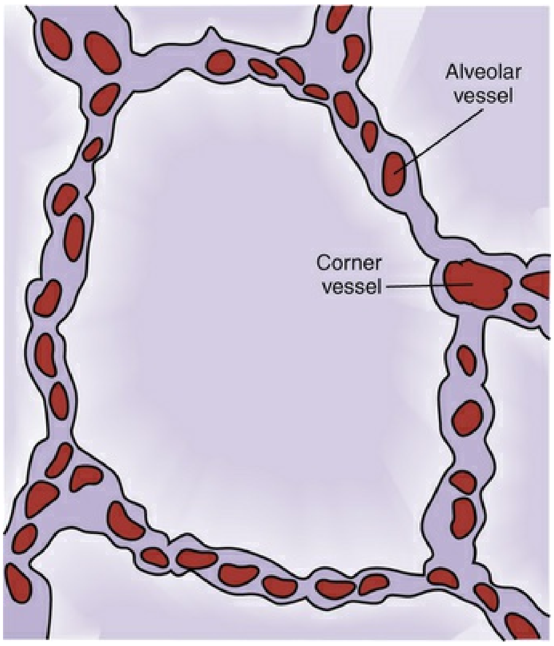

FIG. 34.7 Alveolus is encased in a network of capillaries. Alveolar vessels are those that lie between adjacent alveoli. Corner vessels are those that lie at the intersection of alveolar septa.

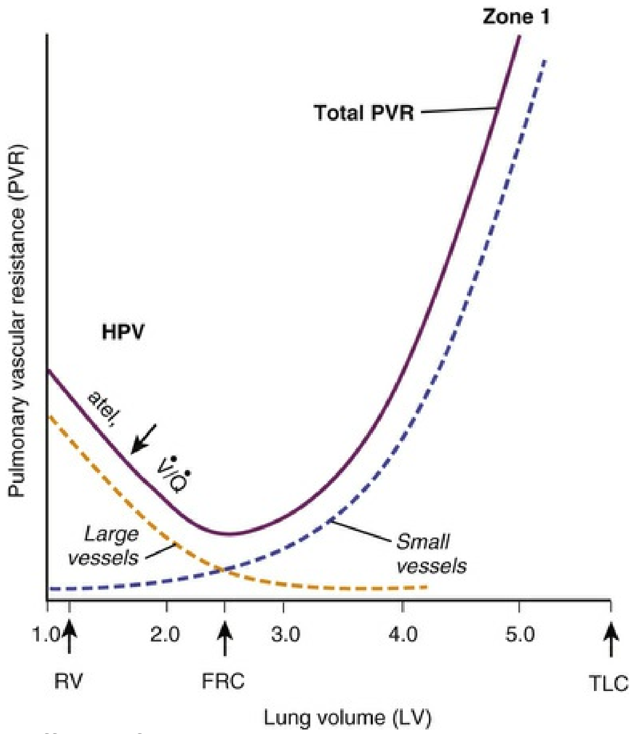

FIG. 34.8 Effects of lung volume on pulmonary vascular resistance *(PVR).* As whole lung is distended from functional residual capacity *(FRC)* toward total lung capacity *(TLC),* PVR rises, predominantly by increasing resistance to flow through the small alveolar vessels that course between adjacent alveoli (alveolar vessels). As whole lung is collapsed from FRC toward residual volume, PVR rises, predominantly by effects on corner vessel that traverse the intersection of alveolar septa. (Modified from Cassidy SS,

Schwiep F. Cardiovascular effects of positive end-expiratory pressure. In: Scharf SM, Cassidy SS, eds. Heart Lung Interactions in Health and Disease, vol 42, Lung Biology in Health and Disease. New York: Dekker; 1989.)

Alveolar Pressure

When alveolar pressure is greater than ambient, as it is during PPV, the vessels that course through alveolar septae between adjacent alveoli can be compressed.[22,23] This behavior is akin to that of a Starling resistor, a collapsible tube traversing a rigid housing (Fig. 34.9). Flow (Q) is propelled through the tube by inflow pressure (P_i) and is opposed by outflow pressure (P_o). The tubing has some intrinsic resistance (R). If the housing is pressurized to a surrounding pressure (P_s), flow through the tube is determined as follows:

$$\text{for } P_s < P_o < P_i, Q = (P_i - P_o)/R \qquad \textbf{Eq. 34.2}$$

$$\text{for } P_o < P_s < P_i, Q = (P_i - P_s)/R \qquad \textbf{Eq. 34.3}$$

$$\text{for } P_o < P_i < P_s, Q = 0 \qquad \textbf{Eq. 34.4}$$

Except when $P_s < P_o$, alveolar pressure appears to modulate local pulmonary blood flow as though it surrounds the pulmonary capillary (Fig. 34.10).

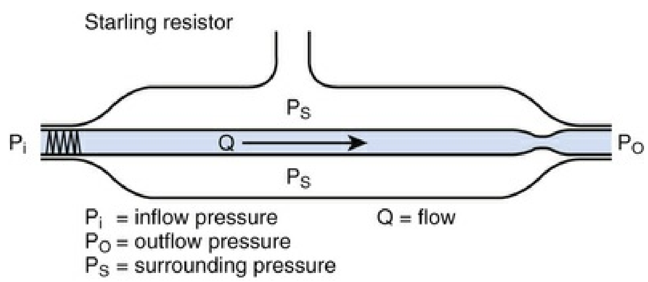

FIG. 34.9 Starling resistor is a compressible conduit traversing a rigid housing, which is pressurized to a surrounding pressure *(P_s)*. Flow *(Q)* traverses the conduit, propelled by inflow pressure *(P_i)* and opposed by outflow pressure *(P_o)* such that driving pressure is ($P_i - P_o$) for $P_s < P_o$. As P_s is increased, it begins to influence flow, but only after it exceeds P_o. At $P_s > P_o$, the driving force for flow becomes ($P_i - P_s$). (Modified from Knowlton FP, Starling EH. The influence of variations in temperature and blood pressure on performance of the isolated mammalian heart. J Physiol. 1912;44:206-219.)

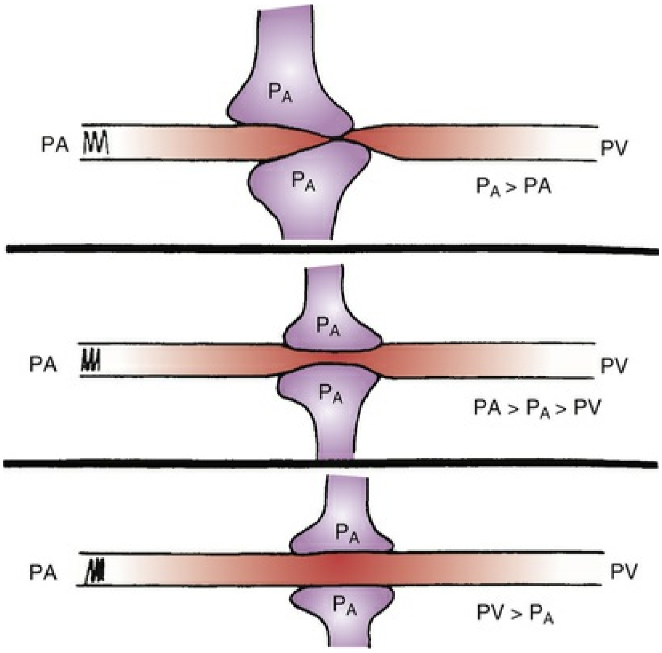

FIG. 34.10 Pulmonary capillaries are, in essence, surrounded by gas-filled alveoli. The influence of alveolar pressure *(P_A)* on regional lung blood flow is similar to the influence of surrounding pressure on flow through a Starling resistor. At ambient values of P_A, pulmonary vein pressure *(PV)* opposes inflow. As P_A rises, it begins to oppose inflow only after P_A > PV. It modulates inflow until P_A reaches hydrostatic inflow pressure *(PA)*, at which point flow ceases.

From this discussion, the degree to which P_s affects pulmonary blood flow is influenced by the magnitude of inflow pressure, which, for the pulmonary capillary, must be adjusted for vertical height. Alveolar pressure causes a greater reduction in flow at low inflow pressure, as seen in hypovolemia, than it does at high inflow pressure, as seen with pulmonary venous hypertension and left heart failure.

Hydrostatic pressure in the lung is a function of vertical height (see Chapter 26).[24] To estimate the hydrostatic inflow pressure of a pulmonary capillary, a pressure equivalent to that exerted by a water column extending from the left atrium to the capillary must be subtracted from the pressure within the main pulmonary artery. The greater the vertical height of the pulmonary capillary, the lower is its inflow pressure and the greater is the attenuation of flow by alveolar pressure. This can produce areas of no flow, especially at peak inspiration, high in the supine lung. Regions of lung with high ventilation/perfusion ratios (V/Q) waste ventilation and can cause hypercapnia (see Chapter 47). Vertical height (h) of the capillary also alters the back pressure to flow. At a left atrial pressure of 10 cm H_2O (7 mm Hg), for example, there is (10 − h) cm H_2O opposing flow up to a vertical height 10 cm above the heart. Above that, there is no back pressure and P_i and P_s alone determine flow through the capillary. Compression of pulmonary capillaries is a local phenomenon. It can divert pulmonary blood flow away from normal lung segments toward consolidated or atelectatic lung segments whose airways do not effectively transmit airway pressure to the alveolus.[25] The application of high PEEP in the presence of lobar pneumonia may increase blood flow through unventilated lung and worsen hypoxemia by this mechanism (Fig. 34.11). From a more positive perspective, PEEP

may relieve atelectasis and improve ventilation, thereby relieving alveolar hypoxic vasoconstriction. Whether PEEP benefits or impairs pulmonary blood flow may depend on the balance of its effect on atelectasis and its effect on alveolar capillaries. It should also be appreciated that while a manipulation of ventilator settings may improve oxygenation and arterial oxygen content, it may also cause cardiac output to decrease resulting in a net reduction in systemic oxygen delivery.

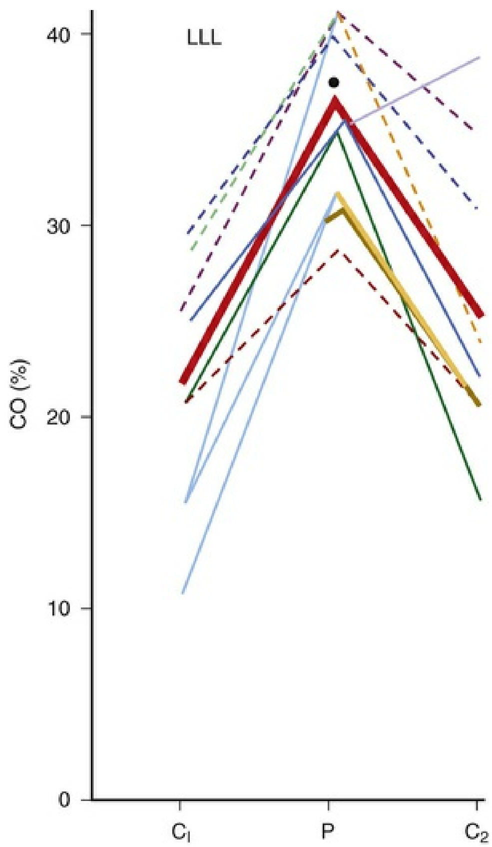

FIG. 34.11 Blood flow to the left lower lobes *(LLL)* of dogs with LLL pneumonia, measured at zero positive end-expiratory pressure *(PEEP)* (C_1), 6–12 cm H_2O PEEP *(P)*, and on cessation of applied PEEP (C_2). PEEP diverted blood flow away from more normal lung toward the consolidated LLL. (From Mink SN, Light RB, Cooligan T, et al. Effect of PEEP on gas exchange and pulmonary perfusion in canine lobar pneumonia. J Appl Physiol. 1981;50:517.)

Regulation of Pulmonary Vascular Resistance

The resistance to flow through a vessel is described by the following:

$$R = 8\eta l / \pi r^4 \quad \textbf{Eq. 34.5}$$

where η is viscosity, l is length, and r is radius. It follows that PVR can be effectively controlled by active changes in vessel radius. Mechanical ventilation may alter blood pH and alveolar oxygen tension (pO_2), both of which influence vessel tone and radius (Fig. 34.12).[26,27]

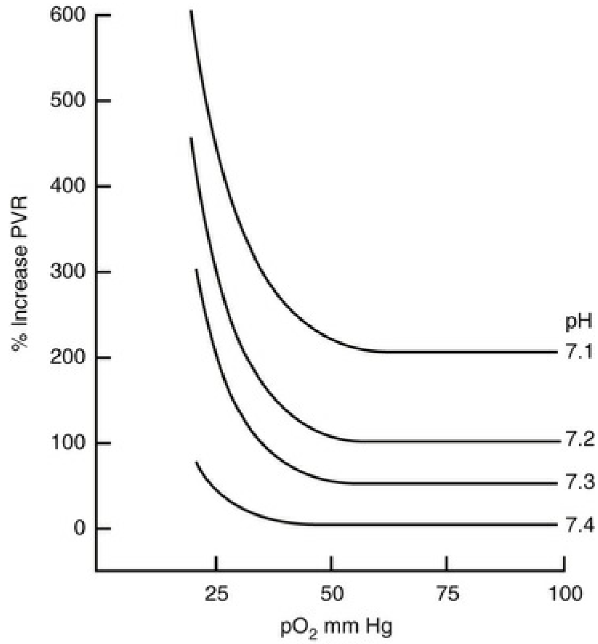

FIG. 34.12 Pulmonary vascular resistance *(PVR)* is a function of both pH and arterial pO_2. (From Rudolph AM, Yuan S. Response of the pulmonary vasculature to hypoxia and H^+ ion concentration changes. J Clin Invest. 1966;45:399.)

Hypoxic pulmonary vasoconstriction is a powerful mechanism for sustaining systemic oxygenation in the face of lung disease.[28-31] Relief of atelectasis and restoration of segmental ventilation not only increases the fraction of the lung that is ventilated but also restores blood flow to those segments by several mechanisms. Segmental alveolar hypoxia is relieved. Segmental volume is restored, which returns segmental vascular resistance toward its volume-dependent nadir. Gas exchange is also improved, favorably altering pH, pCO_2, and pO_2, and thereby reducing global PVR.

Direct Effects of Airway Pressure on Pulmonary Vascular Tone

Pulmonary vessels are stretched by lung inflation. The lung of infant lambs responds to abrupt changes in airway pressure with changes in vascular tone. Abrupt distension of one lung of the intact infant lamb increases the PVR of that lung alone.[32] The resistance change is sensitive to the waveform of the lung distension[33] and persists for some time after relief of distending pressure and return of lung volume to baseline.[34] This effect is calcium channel dependent[35] and resembles a myogenic reflex whereby direct vessel stretch causes constriction.

Left Ventricular Preload

Positive airway pressure can reduce left ventricular (LV) filling via several mechanisms as described earlier. In addition to the potential for limiting systemic venous return, increasing RV afterload, and decreasing RV ejection, positive airway pressure can compromise LV compliance and preload as a result of ventricular interdependence.

Ventricular Interdependence

The right and left ventricles share a common muscle mass and pericardial space. It follows that compliance of either ventricle will be influenced by volume of the other chamber (Fig. 34.13). Increased venous return to the right heart, as occurs during spontaneous inspiration and especially during execution of a Müller maneuver, shifts the interventricular septum to the left, reducing compliance of the left ventricle.[36,37] Similarly, excessive compression of the pulmonary circulation by positive airway pressure may impede RV ejection, causing the right ventricle to dilate and encroach on the left. Reduced LV compliance tends to diminish stroke volume by diminishing LV muscle stretch and ejection force (by the Frank-Starling mechanism).

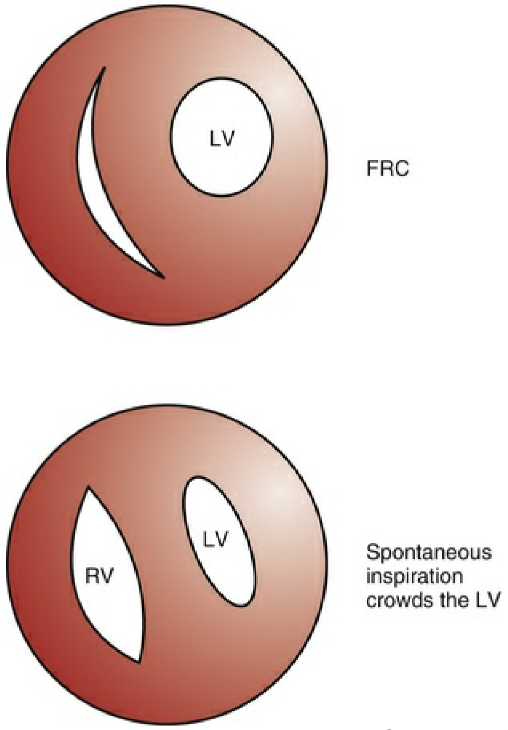

FIG. 34.13 Increasing the diastolic volume of the right ventricle *(RV)* reduces compliance of the left ventricle *(LV). FRC*, functional residual capacity.

Cardiac Crowding

Overinflation of the lungs may crowd the cardiac fossa in which the heart resides. To the extent that this creates a mechanical barrier to cardiac filling, it may reduce LV compliance, end-diastolic volume, and force of contraction.

Left Ventricular Afterload

The left ventricle ejects blood from within the thorax to the extrathoracic arterial system. Most of the resistance to this forward flow resides in the arterioles. From a practical point of view, the pressure in the extrathoracic arteries can be described by the following equations:

$$(P_{artery} - P_{ms}) = Q \times R_{arteriole} \quad \textbf{Eq. 34.6}$$

$$\text{or } P_{artery} = Q \times R_{arteriole} + P_{ms} \quad \textbf{Eq. 34.7}$$

where Q is cardiac output, P_{artery} is inflow pressure before the arteriole, and P_{ms} is outflow pressure after the arteriole as defined for the venous return curve.

When the left ventricle contracts, it creates internal pressure against the closed aortic valve by generating tension in the myocardium that encircles the ventricular chamber. This "wall tension" causes ventricular pressure to rise until it reaches aortic diastolic pressure, opening the aortic valve and ejecting the stroke volume. Creation of wall tension and subsequent shortening of myocardial fibers perform the external mechanical work of the heart (see Chapter 25).

When the heart squeezes, it creates a pressure difference between the ventricle and the juxtacardiac space. In effect, the myocardium creates a transmural pressure to produce a ventricular pressure sufficient to open the aortic valve. Aortic diastolic pressure and external (juxtacardiac) pressure determine the myocardial wall tension needed to open the aortic valve. Both pressures represent afterloads to LV ejection.[38,39]

An infusion of phenylephrine, by raising $R_{arteriole}$, increases the pressure required to open the aortic valve and LV afterload (Fig. 34.14). This increases the wall tension the heart must generate to eject blood.

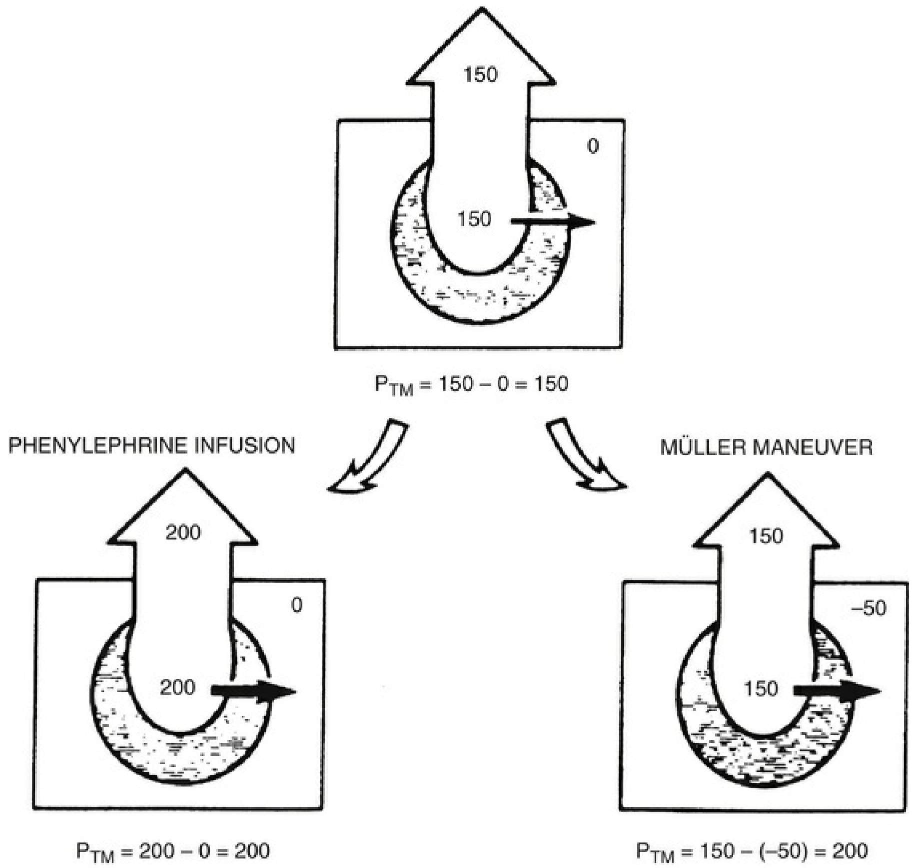

FIG. 34.14 Negative pressure in the juxtacardiac space (Müller

maneuver) increases the wall tension required to eject blood into the aorta. This respiratory maneuver acts like a phenylephrine infusion to increase left ventricular afterload. (From Buda AJ, Pinsky MR, Ingels NB Jr, et al. Effect of intrathoracic pressure on left ventricular performance. N Engl J Med. 1979;301:453.)

The Müller maneuver, forced inspiration against a closed glottis, does the same thing. It reduces juxtacardiac pressure, thereby raising the transmural pressure required to open the aortic valve. Thus the Müller maneuver also increases the afterload of the left ventricle.

Positive pressure inspiration or application of PEEP may raise juxtacardiac pressure to such an extent that the wall tension required to open the aortic valve is diminished. Mechanical ventilation may, therefore, reduce the afterload of the left ventricle.

The net effect of positive pressure inspiration is often augmentation of LV stroke volume and cardiac output. Arterial pressure is commonly observed to rise during positive pressure inspiration, whereas it falls during spontaneous inspiration. These are largely effects of afterload on stroke volume.

Cardiac Contractility

Studies of the effects of positive airway pressure on LV contractility have yielded conflicting results. Certainly ventilator changes in preload and afterload have secondary effects on stroke volume, but independent effects of positive airway pressure on LV contractility have not been consistently demonstrated. Negative inotropic effects modulated by reflexes, mediators, or alterations in coronary blood flow have been described,[40-45] but most animal and human studies fail to show that positive airway pressure has any primary effect on myocardial contractility.[46-49]

It has been suggested that high levels of PEEP may compress coronary vessels, cause myocardial ischemia, and thereby impair ventricular function.[50-52] LV myocardium is perfused predominantly in diastole. To the extent that juxtacardiac pressure exceeds diastolic pressure in the coronary sinus, such an effect is plausible. This assertion appears more compelling for patients in shock and for those with intrinsic coronary blood flow limitations than for otherwise normal individuals.

Preload Dependence Versus Afterload Dependence

The expected effects of a rise in airway pressure are as follows:

1. Decreased filling of the right ventricle acts to decrease RV stroke volume.

2. Pulmonary vascular compression increases RV afterload and acts to decrease RV stroke volume.

3. These effects may either increase or decrease RV size, depending on which effect predominates; if RV volume increases, ventricular interdependence adversely impacts LV function.

4. Both diastolic displacement of the interventricular septum toward the left ventricle (with resultant crowding of the left ventricle) and crowding of the juxtacardiac space by the expanding lungs reduce LV compliance. Both factors act to decrease LV filling

and stroke volume.

5. The fall in LV afterload that results from increased juxtacardiac pressure acts to increase LV stroke volume.

These effects of positive airway pressure may have conflicting effects on stroke volume, so their aggregate effect on cardiac output is not entirely predictable.

In general, positive airway pressure has its most pronounced effect on the right heart; therefore positive airway pressure reduces cardiac output in most patients. This effect is greatest in patients who are hypovolemic because the driving pressure for systemic venous return ($P_{ms} - P_{ra}$) is more sensitive to change in P_{ra} when P_{ms} is low. In addition, pulmonary venous pressure is low and PPV increases the proportion of lung units where P_s (alveolar) > P_i, increasing RV afterload and decreasing RV ejection. In adults, the P_{ra} threshold (at zero PEEP) below which increasing airway pressure reduces cardiac output is approximately 12 mm Hg.[53] Another definition of preload dependence is responsiveness to vascular volume infusion. By this definition, when the dominant effect of positive airway pressure is to impede right heart filling, vascular volume infusion raises cardiac output. Four measurable parameters (Fig. 34.15) predict responsiveness to vascular volume infusion: (1) variation of pulse pressure over the respiratory cycle (Maximum − Minimum), (2) arterial systolic pressure, (3) P_{ra}, and (4) pulmonary artery wedge pressure.[54] Of these parameters, the inspiratory increase in arterial pulse pressure is the most sensitive and specific predictor of "preload dependence" (by receptor operating characteristic curve) (Fig. 34.16). Greater than 15% inspiratory rise in pulse pressure appears to identify adults with preload dependence during positive pressure ventilation.[55]

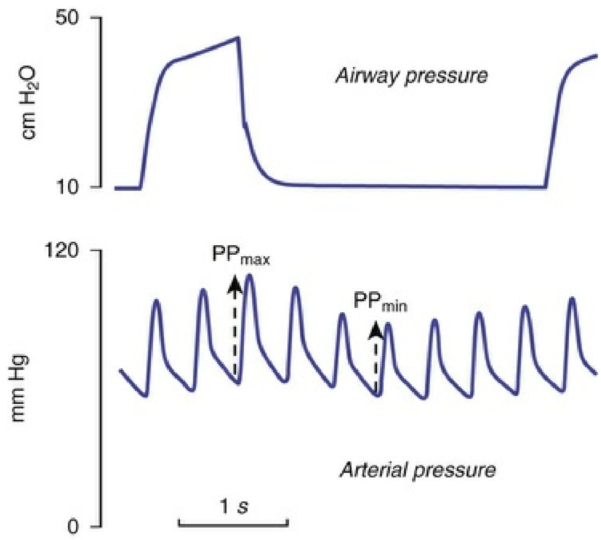

FIG. 34.15 Positive pressure inspiration generally raises aortic pulse pressure *(PP)*, systolic pressure *(SP)*, and diastolic pressure *(DP)*, as well as right atrial pressure and pulmonary artery wedge pressure. (From Michard F, Chemla D, Richard C, et al. Clinical use of respiratory changes in arterial pulse pressure to monitor the hemodynamic effects of PEEP. Am J Respir Crit Care Med. 1999;159:935.)

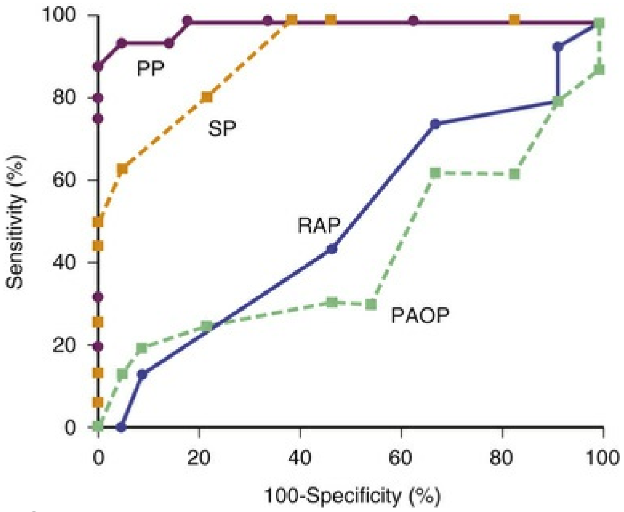

FIG. 34.16 Septic patients on positive end-expiratory pressure were challenged by volume infusion. In response to volume loading, some patients had a greater than 15% increase in cardiac index. These responsive patients were deemed preload dependent. The sensitivity and specificity of variation in pulse pressure *(PP)* across the respiratory cycle as a predictor of responsiveness to volume loading yielded a near-perfect receiver operating characteristic curve. Greater than 15% inspiratory rise in PP appears to identify adults with preload dependence during positive pressure ventilation. *PAOP*, pulmonary artery occlusion pressure; *RAP*, right atrial pressure; *SP*, systolic pressure. (From Michard F, Boussat S, Chemla D, et al. Relation between respiratory changes in arterial pulse pressure and fluid responsiveness in septic patients with acute circulatory failure. Am J Respir Crit Care Med. 2000;162:134.)

One might expect the converse also to apply. Reduced magnitude of the effects of PPV on RV filling or augmented effects on LV ejection may make the patient "afterload dependent." Patients who have high blood volume, such as those in congestive cardiac failure or those with chronic anemia, should have high P_{ms} and decreased sensitivity to changes in P_{ra}.[56] Moreover, the patient with poor LV contractility may greatly benefit from the afterload reduction of PPV.[57] If positive airway pressure enhances the ejection of blood into the systemic circulation, this may directly reduce left atrial pressure. From these considerations, improved cardiac output reduces P_{ra} enhancing systemic venous return (see Fig. 34.1B). When favorable effects on LV ejection act to reduce right and left atrial pressures, cardiac output improves. Such a patient might be thought of as "afterload dependent."

Fluid Responsiveness During Positive Pressure Ventilation

In the ICU, whether volume infusion will augment cardiac output or merely contribute to vascular volume overload is often a vital issue. In adult patients receiving PPV, about half of all hemodynamically unstable critical care patients are not volume responsive.[58] Traditional guides to volume resuscitation have focused on measurement of cardiac filling pressures and responses to fluid challenges. In critically ill patients and in normal subjects, the stroke volume response to vascular volume infusion is poorly predicted by measurement of either right atrial or

pulmonary artery occlusion pressure.[59] Much recent interest has focused on minimally invasive estimation of likelihood of responding to fluid infusion.

The cardiopulmonary interactions described previously can be used to predict response to fluid challenge. The change in stroke volume over the course of the positive pressure respiratory cycle strongly predicts fluid responsiveness; the greater the percentage change in stroke volume, the greater the response to volume infusion.[60] Similar relations have been shown between fluid responsiveness and respiratory variation in aortic blood flow velocity[61] and arterial pulse pressure.[53] Inspiratory collapsibility of the inferior[62] and superior[63] vena cavae has also been shown to predict volume responsiveness. The strong linear relationship of increase in cardiac index after fluid resuscitation to preinfusion pulse pressure variability over the respiratory cycle (ΔPP) is shown in Fig. 34.17, which depicts data from 40 mechanically ventilated adults with acute circulatory failure related to sepsis.

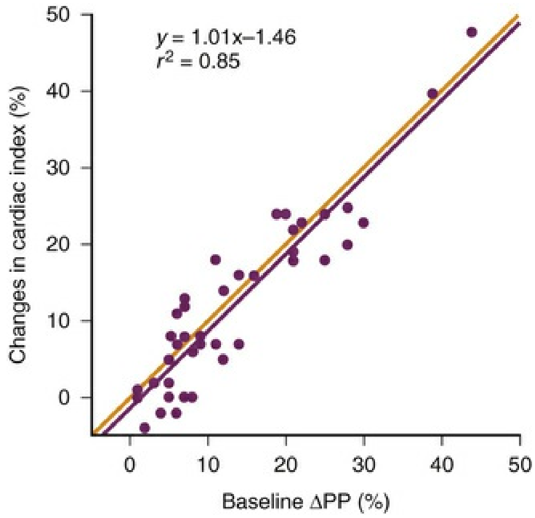

FIG. 34.17 Relationship between ΔPP before volume expansion (baseline) and % change in cardiac index in 40 adult patients with septic shock during mechanical ventilation. Volume expansion comprised 500 mL 6% hydroxyethyl starch. ΔPP = 2 × (Peak arterial pulse pressure − Lowest arterial pulse pressure)/(Peak PP + Lowest PP). (From Michard F, Boussat S, Chemla D, et al. Relation between respiratory changes in arterial pulse pressure and fluid responsiveness in septic patients with acute circulatory failure. Am J Respir Crit Care Med. 2000;162:134.)

This same parameter, change in arterial pulse pressure over the respiratory cycle, can be used to estimate the effect of PEEP on cardiac index. The strong linear relationship of ΔPP to PEEP-induced change in cardiac index is shown in Fig. 34.18.

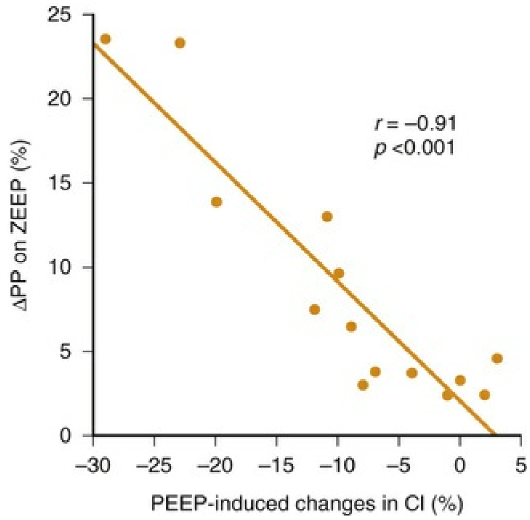

FIG. 34.18 Relationship between ΔPP on zero PEEP and % decrease in cardiac index on application of 10 cm H_2O PEEP. ΔPP = 2 × (Peak arterial pulse pressure − Lowest arterial pulse pressure)/(Peak PP + Lowest PP). (From Michard F, Chemla D, Richard C, et al. Clinical use of respiratory changes in arterial pulse pressure to monitor the hemodynamic effects of PEEP. Am J Respir Crit Care Med. 1999;159:935.)

Changes in cardiac index induced by either fluid resuscitation or by application of PEEP appear to be predicted by measurement of ΔPP.[54] In general, in these patients, the greater the ΔPP, the more preload dependent the patient is to PEEP and the more responsive to fluid resuscitation.

Elevated Work of Breathing and the Circulation

During quiet respiration, the heart has no difficulty satisfying the demand of the respiratory muscles for perfusion and oxygen delivery. In respiratory failure, however, respiratory muscle perfusion may not be adequate. The diaphragm and accessory muscles of respiration are taxed to the limit by respiratory distress. Unlike cardiac muscle, respiratory muscles can accumulate a limited oxygen debt, and persistent hypoperfusion may interfere with their ability to perform the requisite work of breathing. In addition, in a low cardiac output state a competition among viscera for blood flow is created. The brain, myocardium, and respiratory pump lack adrenergic receptors and, under intense neurohormonal activation, do not experience an increase in resistance to flow and thus compete for a limited cardiac output. Roussos and colleagues[64-66] demonstrated in animal models of cardiogenic and septic shock that mechanical ventilation and the unloading of the respiratory pump lead to a significant redistribution of blood flow from muscles of respiration to other vital organs, including the brain. Because it unloads the respiratory pump and decreases LV afterload, mechanical ventilation should be considered an essential tool in the armamentarium for treating heart failure and shock.

Pulsus Paradoxus in Respiratory Distress

Arterial pressure normally falls during spontaneous inspiration, which is best explained as a result of increasing LV afterload at a time in the respiratory cycle when ventricular interdependence restricts LV filling. It is well known that

pericardial tamponade causes accentuation of the normal inspiratory decrease in systemic blood pressure, a phenomenon known as *pulsus paradoxus.* This phenomenon has been attributed to accentuation of normal ventricular interdependence, in the face of restricted biventricular diastolic volume of the heart. During loaded spontaneous inspiration, as in the Müller maneuver or in the presence of inspiratory airway obstruction (eg, croup), the inspiratory fall in juxtacardiac pressure is exaggerated and LV afterload is accentuated. Again, the result is pulsus paradoxus, an accentuated drop in blood pressure during inspiration.

The increase in blood pressure that occurs during positive pressure inspiration has been termed *reverse pulsus paradoxus*. This finding has been attributed to LV afterload reduction by the rise in juxtacardiac pressure that occurs during positive pressure inspiration.[67] Reverse pulsus paradoxus is a normal finding during positive pressure ventilation but may be accentuated in afterload-dependent states (eg, LV systolic dysfunction) as discussed earlier in the "Preload Dependence Versus Afterload Dependence" section).

Effects of Breathing on Measurement of Hemodynamic Parameters

Because hemodynamic measurements vary with respiration, mechanical ventilation may complicate assessment of cardiac function. Yet it may not be advisable to discontinue PEEP or mechanical ventilation to assess hemodynamics. Measuring vascular pressures at a consistent time in the respiratory cycle is usually sufficient. End-expiratory measurements are generally used because airway pressures are least at that time and hemodynamic measurements most closely approximate those at FRC.

It should be understood that the effects of mechanical ventilation on circulation are not merely artifactual. They are real. There is no greater accuracy of measurements made off the ventilator. Measurements performed after ventilator disconnect are subject to the effects of respiratory dysfunction and instability. Besides, the values of the hemodynamic parameters that are of interest are those that exist during stable mechanical ventilation.

A special circumstance can occur when a balloon flotation catheter with its tip in zone I lung is used to measure pulmonary artery pressure and when such a catheter with its tip in zone I or II lung is used to measure pulmonary artery wedge pressure.[68] Under such circumstances, airway pressures that exceed vascular pressures may be erroneously reported as vascular pressures.

Effects of Cardiovascular Function on Respiration

Shock States and Respiratory Function

Shock of any cause diminishes perfusion of respiratory muscles and can lead to respiratory failure and respiratory arrest. It also causes metabolic acidosis, which constricts pulmonary vessels and opposes lung blood flow.[69,70] Acidosis is a potent

stimulus of respiratory effort and contributes to tachypnea and respiratory distress, which in turn worsen the demand on the heart. Shock is injurious to both heart and lung, and one final common pathway to recovery is the initiation of mechanical ventilation, which benefits both organ systems.

Hypovolemic shock can create extreme preload dependency.[71] In hypovolemic shock, diastolic blood pressure may fall during positive pressure inspiration, impairing coronary perfusion. This may cause myocardial ischemia and worsen cardiac function.

Cardiogenic shock, by reducing oxygen delivery to tissues, elevates percent tissue oxygen extraction from the blood. The resultant decline in venous oxygen tension has a paradoxical effect. It increases the efficiency of pulmonary blood flow by allowing greater oxygen uptake per unit of pulmonary blood flow. That is, the more desaturated the blood that enters the pulmonary circulation, the more new oxygen it can upload. This process requires that alveolar pO_2 not limit the amount of oxygen available for uptake and is one reason to administer oxygen to patients suffering cardiorespiratory failure.

Congestive Heart Failure

All that has been said about shock is equally true of congestive heart failure (CHF). In fact, there is a continuum from CHF to cardiogenic shock. CHF elicits physiologic responses that attempt to restore and maintain an adequate cardiac output. As these homeostatic responses are exhausted, cardiac output becomes inadequate and the patient develops obvious manifestations of cardiogenic shock and respiratory failure.

In addition to the impact of shock on respiratory function and reserve, CHF generally causes fluid retention and pulmonary edema. Treatment of cardiogenic shock by vascular volume expansion may, by augmenting cardiac filling pressures, improve cardiac output at the expense of pulmonary edema, which leads to elevated airway resistance, atelectasis, intrapulmonary shunt, and impaired oxygenation. Impaired respiratory mechanics leads to exaggerated negative pressure breathing and increased LV afterload while increasing circulatory demands by increasing respiratory muscle oxygen demand. Further, as the work of breathing increases, neurohormonal pathways are stimulated, which contribute importantly to increases in LV afterload, as described earlier.

PPV with PEEP improves lung function and oxygenation, eliminates exaggerated negative swings in intrathoracic pressure, and reduces sympathetic nervous system activation. In contrast to hypovolemic shock, cardiogenic shock generally causes elevated atrial pressures. When this is the case, pulmonary blood flow may be insensitive to airway pressures during positive pressure ventilation as a disproportionate number of lung units have $Pv > P_s$ (alveolar pressure). The patient is then usually afterload dependent and responds favorably to the afterload reducing effects of PPV. When treating the patient with CHF during PPV, there is a risk of worsening pulmonary edema during fluid resuscitation. It is wise to assess pulse pressure, as well as systolic and diastolic pressures, to predict volume responsiveness before administering volume.[72] These parameters may also prove useful in assessing the impact of changes in intrathoracic pressure on cardiac index.[54]

Cardiomyopathies and Congenital Heart Disease

Hypertrophic cardiomyopathy is characterized by intact LV systolic function but has varying degrees of diastolic dysfunction that may compromise output due to inadequate ventricular filling.[73] Thus the impact of increases in intrathoracic pressure on systemic venous return may not be tolerated. If pulmonary venous pressure is elevated secondary to impaired LV compliance, the impact of PPV and lung volumes on pulmonary vascular resistance will be mitigated as the proportion of lung units with $Pv > P_s$ increases. Hypertrophic cardiomyopathy may also obstruct LV outflow, either at rest or with exertion. PPV may not be tolerated as a decrease in preload and afterload leads to a decrease in ventricular operating volumes, exacerbating the obstruction.[74] Restrictive cardiomyopathies invariably have severe abnormalities of ventricular diastolic dysfunction. One would also expect these patients to not tolerate PPV due to its impact on systemic venous return.

The impact of intrathoracic pressure on ventricular diastolic disease is exemplified in some patients following repair of tetralogy of Fallot where varying degrees of RV diastolic dysfunction are common. In a subgroup of these patients, the degree of impairment is severe and has been termed *restrictive physiology*. In these patients, atrial systole causes RV diastolic pressure to rise above pulmonary arterial diastolic pressure generating pulmonary arterial flow during ventricular diastole. LV systolic function is, in most cases, normal; thus the primary impact of changes in intrathoracic pressure is on the right heart. Further, pulmonary venous pressure should not be elevated. Therefore PPV may be expected to increase the proportion of lung units with P_s (alveolar) > P_i, increasing RV afterload, which may not be tolerated. Shekerdemian and colleagues[75] demonstrated a significant increase in cardiac output when patients were converted from PPV to negative pressure ventilation using a cuirass.

Glenn and Fontan Procedures

Hearts that cannot support two separate circulations after repair (univentricular hearts and hearts having one hypoplastic ventricle) are often palliated and then repaired by routing systemic venous return directly to the lung without an intervening subpulmonic pumping chamber (Glenn and Fontan procedures). In the Glenn circulation, pulmonary blood flow is derived from venous drainage from the upper extremities and brain by way of the superior vena cava flow and is thus sensitive to changes in intrathoracic pressure and its impact on the superior vena cava–pulmonary artery confluence, as well as lung volume and its impact on pulmonary vascular resistance. One would expect pulmonary blood flow and oxygenation to improve during spontaneous respiration. In the Glenn circulation the inferior vena cava drains directly to the single ventricle, and while systemic venous return is adversely affected by increases in intrathoracic pressure, it is not impacted by the lack of a subpulmonic pumping chamber and thus systemic output is generally well maintained following the Glenn procedure.

In the Fontan circulation, venous return from the lower body is diverted directly to the pulmonary arteries and thus all systemic venous return must traverse the pulmonary circulation without a subpulmonic pumping chamber to maintain adequate ventricular filling. The P_{ms} drives systemic venous return from the venous

reservoirs to the central venous structures as in a normal circulation but is also responsible for driving systemic venous return across the pulmonary circulation to the single ventricle.[76]

Decreases in the common atrial pressure during the cardiac cycle contribute to the pressure gradient driving pulmonary venous return.[77] Because the pulmonary circulation and single ventricle reside entirely within the chest, changes in intrathoracic pressure do not contribute to driving pulmonary blood flow other than by altering the pressure gradient for systemic venous return to the vena cava–pulmonary artery confluence, as well as by altering the effective compliance of the ventricle as in the normal circulation. Shekerdemian and colleagues[78] demonstrated the importance of intrathoracic pressure in the Fontan circulation. Immediately following the Fontan procedure, negative pressure ventilation using a cuirass significantly improved cardiac output compared with PPV. Williams and colleagues[79] demonstrated the sensitivity of the Fontan circulation to PPV by exposing the inverse relationship between pulmonary vascular resistance and cardiac output with progressive increases in PEEP.

CHAPTER 35

Disorders of Cardiac Rhythm

Frank A. Fish, Prince J. Kannankeril

PEARLS

- Arrhythmias may result from ongoing therapies; ask, "What's the DEAL?"
- *D*rugs and drips
- *E*lectrolytes
- *A*irway and acid base
- *L*ines
- Appropriate diagnosis is key. Always attempt to document arrhythmia in multiple leads before instituting therapy.
- For ventricular fibrillation or pulseless ventricular tachycardia, begin cardiopulmonary resuscitation and defibrillate immediately.
- Involve a cardiologist before initiating (chronic) antiarrhythmic drug therapy.
- Whenever possible, use available means to document atrial rate to discern correct ventricular-atrial relationship.
- "Supraventricular tachycardia" is a nonspecific electrocardiographic pattern. Multiple types of supraventricular tachycardia exist, and appropriate therapy depends on appropriate diagnosis.
- Whenever possible, opt for therapies that maintain atrioventricular synchrony.

Cardiac arrhythmias are frequently encountered in the intensive care setting. This chapter reviews diagnosis and management of arrhythmias representing a primary disease process and those that occur secondary to other conditions or therapies (Table 35.1).[1,2] Prompt restoration of hemodynamic stability concurrent with appropriate identification of the arrhythmia mechanism and predisposing factors is emphasized while providing a broader overview of arrhythmia mechanisms and their associated presentations in pediatric patients.

TABLE 35.1

Classification of Arrhythmias by Type and Basis

Arrhythmia	Primary	Secondary
Ventricular premature beats and supraventricular premature beats	+++	+++
Sinus bradycardia, sick sinus syndrome	++	++
Incomplete AV block		
Mobitz I	++	+++
Mobitz II		++
Congenital third-degree AV block	+++	++
Acquired third-degree AV Block		++
Paroxysmal SVT (AV reentrant tachycardia, AV nodal reentrant tachycardia)	+++	
Ectopic atrial tachycardia	++	
Atrial flutter and intraatrial reentry	++	+++
Atrial fibrillation	+	+++
Chaotic atrial tachycardia		++
Junctional ectopic tachycardia	+	+++
Monomorphic ventricular tachycardia	++	++
Torsades des pointes	+	+
Ventricular fibrillation	+	++
Bidirectional ventricular tachycardia	++	+

AV, atrioventricular; *SVT*, supraventricular tachycardia; +++, typical; ++, occasional; +, rare.

Classification of Arrhythmias

Arrhythmias can be classified according to rate, electrocardiographic findings, and, when possible, the underlying electrophysiologic mechanisms. Electrocardiographically, arrhythmias can be characterized as bradycardias, extrasystoles, or tachycardias. Bradycardias are further subdivided by the level of dysfunction (eg, sinus node dysfunction vs. atrioventricular [AV] block) and by the ensuing rhythm (sinus, junctional, or idioventricular). Extrasystoles and tachycardias are categorized as atrial, junctional, or ventricular in origin. Tachycardias are initially characterized by the level of origin (supraventricular vs. ventricular), by electrocardiographic pattern, and functional mechanism: reentry, automaticity, or triggered activity. Whereas most treatment algorithms assume a reentrant mechanism, abnormal triggering and automaticity may be particularly important in the critically ill. Although differentiating between these mechanisms is sometimes difficult, it may be essential in guiding appropriate therapy, especially if initial therapies prove ineffective.

Bradycardias

Appropriate Versus Normal Heart Rate

Since normal heart rate ranges vary tremendously during childhood as a function of age and autonomic tone, “appropriate” heart rate is a more useful concept than “normal” heart rate. Thus any inappropriately fast or slow rates for a given circumstance warrant evaluation for factors affecting the sinus rate such as pain, agitation, respiratory insufficiency, oversedation, anemia, or acidosis, as well as the potential for a nonsinus arrhythmia.

Sinus Bradycardia and Sinus Pauses

Sinus bradycardia may result from high vagal tone, hypothermia, acidosis, increased intracranial pressure, drug toxicities, or direct surgical trauma to the sinoatrial (SA) node. Primary sinus node dysfunction in childhood is rare but has been described.[3]

Transiently profound sinus bradycardia or prolonged sinus pauses of several seconds duration may be caused by intense vagal episodes, such as those occurring during neurocardiogenic syncope, apnea, or endotracheal suctioning. When clearly correlated with a vagal stimulus, pacing can usually be deferred. However, the hemodynamically tenuous patient with persistent or recurring bradycardias may warrant vagolytic, sympathomimetic, or pacing therapies.

It is important to recognize pauses due to blocked premature atrial depolarizations (PACs) where premature P waves may be obscured in the preceding T wave. Similarly, blocked PACs occurring in a bigeminal pattern may mimic sinus bradycardia. In cardiac patients, sinus node dysfunction may be the result of surgical injury or heterotaxy syndromes. Sinus bradycardia can also be a manifestation of long QT syndrome in infancy and of channelopathies.[4]

Atrioventricular Block

AV block is characterized as first-degree, second-degree, and third-degree, according to whether there is conduction delay, intermittent block, or complete loss of conduction between atria and ventricles. As with sinus bradycardia, AV conduction delay may be the result of intense vagal tone, metabolic derangements, drug toxicity, or direct injury to the AV node.

Second-degree block can be further characterized as Mobitz type I or Mobitz type II. In Mobitz I (Wenckebach conduction) there is progressive prolongation of the PR before block. It may be best recognized by comparing the last PR interval before block with the next conducted PR. Mobitz I usually represents block in the AV node and is less likely to progress suddenly to high-grade block. In some settings, such as in well-conditioned athletes, Mobitz I block may be benign.

Mobitz type II AV block is characterized by abrupt failure to conduct without prior lengthening of the PR interval. It is usually attributed to block within the His bundle and may portend a greater potential for sudden progression to complete AV block. Type II block may be more ominous and may require more aggressive and preemptive intervention with pacing.

Higher grades of second-degree AV block are best characterized by the ratio of atrial to ventricular depolarizations (2 : 1, 3 : 1, 4 : 1, etc.). Unless the onset is displayed, it cannot be characterized as Mobitz I or Mobitz II and the level of block cannot be inferred. High-grade AV block during sinus rhythm is usually pathologic but can occur as a normal response to rapid atrial tachyarrhythmias such as atrial flutter. Likewise, vagally mediated AV block may result in transient high-grade block (although the sinus rate usually slows concurrently).

Complete or third-degree AV block represents complete loss of AV conduction, usually with a junctional or idioventricular escape rhythm that is regular but may be quite slow. Changes in the RR interval usually indicate intermittent conduction during second-degree block (Fig. 35.1) or a junctional rhythm with slower atrial rate and intermittent AV conduction (sinus capture complexes).

FIG. 35.1 Complete atrioventricular (AV) block, presumably congenital, in an asymptomatic 9-year-old with slow resting heart rate. Note the regular RR interval, which confirms complete rather than incomplete (second-degree) AV block.

Bundle branch block patterns occur when impaired conduction in the specialized intraventricular conduction system results in delayed right or left ventricular depolarization, resulting in an aberrant widened QRS complex. Bundle branch block and AV block sometimes represent normal physiologic responses to abrupt shortening of the cycle length (as with premature atrial systoles or tachycardia initiation) or may result from drug effects, surgical injury, or primary disease within the specialized conduction tissue.

Escape Rhythms and Accelerated Rhythms

In the presence of sinus bradycardia or AV block, slower subsidiary rhythms typically emerge from the atrium, AV node, His-Purkinje system, or ventricular myocardium. When slower than the appropriate sinus rate, they are referred to as escape rhythms (atrial, junctional, or idioventricular). Similar rhythms may emerge and compete with an appropriate sinus rhythm, in which case they are referred to as an *accelerated rhythm.* Such rhythms can result from increased adrenergic tone, intrinsic mechanisms, or drug infusions. It is important to distinguish these accelerated subsidiary rhythms from escape rhythms resulting from AV block. Only rarely does an accelerated junctional or ventricular rhythm result in significant symptoms in a healthy child.[5] However, in the critically ill patient, atrial pacing at a slightly faster rate may be warranted to reestablish AV synchrony if cardiac output is compromised. The distinction between these accelerated junctional or ventricular rhythms and pathologic tachycardia can sometimes be arbitrary but is usually determined by the similarity in rates and gradual transitions between the accelerated rhythm with the normal sinus rhythm.

Tachycardias

Classification by Mechanism

While sinus tachycardia is the most common tachycardia of ill patients, pathologic tachycardias can occur due to three basic mechanisms: reentry, automaticity, or triggered. *Reentry* accounts for most forms of SVT, including atrial flutter and most sustained ventricular tachycardias (VTs). Reentrant tachycardias display an abrupt onset and termination, usually maintaining a relatively fixed rate. In contrast, *automatic* tachycardias arise from ectopic foci within the atrium, AV node, or ventricles and display more gradual changes in rate with “warm up” and “cool down” at onset and offset. *Triggered* tachycardias result from abnormal secondary depolarizations (afterdepolarizations). They typically occur as bursts of tachycardia and may be recognized by their dependence on underlying heart rate for initiation. Triggered activity is especially important in several specific situations such as cardiac glycoside toxicity (delayed afterdepolarizations) and drug-induced long QT syndromes (early afterdepolarizations), and they also are important in many hereditary arrhythmia syndromes. The dependence of triggered activity on underlying heart rate can sometimes be exploited therapeutically because either raising or lowering the underlying rate may suppress the tachycardia.

Classification by Site

Tachycardias usually are first characterized as either supraventricular or ventricular. However, both supraventricular and VTs include a diverse group of arrhythmias with varying substrates, mechanisms, and electrocardiographic features that become increasingly important when simple treatment algorithms fail or when arrhythmias become recurrent and require repeated or ongoing therapies.

Supraventricular Tachycardias

“Supraventricular tachycardia” (SVT), “paroxysmal atrial tachycardia,” and “paroxysmal supraventricular tachycardia” (PSVT) are descriptive but nonspecific terms commonly used to describe any regular tachycardia (usually in excess of 200–220 beats/min) with normal QRS morphology and P waves that are either indiscernible or immediately follow the QRS complex. In otherwise healthy neonates and children this pattern usually represents a “reciprocating” tachycardia due to AV nodal reentry or AV reentry using an accessory connection (see next section). However, these same electrocardiographic features can be produced by a more diverse array of tachycardia mechanisms.[6] Furthermore, the most common SVTs can sometimes display variable patterns, including a “normal” PR interval, intermittent 2 : 1 conduction (in the case of AV node reentry), or a widened QRS, either because of rate-related bundle branch block or antegrade conduction through an accessory connection. Therefore it is most useful to adopt a broad and inclusive definition of SVT, which allows inclusion of nonreciprocating mechanisms such as atrial tachycardia, atrial flutter and fibrillation, junctional tachycardias, and wide QRS SVTs.

Atrioventricular Reciprocating Tachycardias (AV Reentry)

AV reciprocating tachycardias use one or more accessory AV connections in a

reentrant circuit between the atria and ventricles. By definition, they display a fixed 1 : 1 AV relationship. In the most common pediatric mechanism of SVT, referred to as *orthodromic reciprocating tachycardia* (ORT), the AV node serves as the antegrade limb and retrograde conduction is over the accessory pathway,[6,7] with retrograde P waves immediately following each QRS complex.

Permanent junctional reciprocating tachycardia (PJRT) is a variant of ORT in which the accessory pathway displays slow, decremental ("AV node-like") conduction.[8] The result is typically a slower, more incessant tachycardia displaying a short or normal PR interval. In a single-lead rhythm strip, PJRT may mimic sinus tachycardia, although a 12-lead electrocardiogram (ECG) reveals atypical P wave morphology with P-wave inversion in the inferior leads. Repetitively spontaneous termination and prompt reinitiation are common features aiding in tachycardia recognition (Fig. 35.2).

FIG. 35.2 Supraventricular tachycardia resulting from the permanent form of junctional reciprocating tachycardia. Note the slow rate, long RP and short PR interval, and inverted P waves in electrocardiogram leads II and III. At rest, this rhythm often shows incessantly repetitive termination (with retrograde block), followed by immediate reinitiation (after single, isolated sinus complexes). With exercise, this rhythm is often faster and sustained, rendering it electrocardiographically indistinguishable from the atypical form of nodal reentry.

In many patients with ORT, the accessory pathway can only conduct retrograde and is thus clinically evident only during tachycardia or during ventricular pacing; the QRS is normal during sinus rhythm. However, if the accessory connection conducts antegradely during sinus rhythm, "preexcitation" results in a delta wave: shortened PR interval and slurring of the QRS upstroke, the hallmark of Wolff-Parkinson-White (WPW) syndrome. Many patients with congenital heart disease may display a slurred QRS upstroke due to intraventricular conduction delay, which can be readily distinguished from WPW if the PR is prolonged.

Antidromic reciprocating tachycardia (ART) is a much less common form of AV reentry in which the circuit is reversed: Antegrade conduction from atrium to ventricle is over the accessory connection, resulting in a very wide ("maximally preexcited") QRS. ART can be difficult to distinguish from VT. Because it is a potentially more dangerous rhythm than ORT, it is most appropriately managed as VT in the acute setting. However, by definition, patients experiencing ART will display the WPW pattern after sinus rhythm is restored.

A specific form of antidromic AV reentry uses a Mahaim fiber. In the current era,

this usually refers to a connection traversing the right AV ring, which displays decremental or AV nodelike conduction (atriofascicular connection). It results in wide QRS tachycardia resembling a left bundle branch block pattern and is particularly common in patients with Ebstein anomaly. Though usually responsive acutely to maneuvers interrupting AV node conduction, electrophysiologic study is required to confirm the diagnosis and distinguish it from VT or other forms of SVT with aberrancy.

Atrioventricular Nodal Reentrant Tachycardia

AV nodal reentrant tachycardia (AVNRT) is the second most common cause of SVT in older children and young adults without WPW syndrome or structural heart disease. It is seen less commonly in infants.[6,7] This tachycardia is attributed to so-called "dual AV nodal physiology" in which two or more separate inputs into the AV node (slow and fast pathways) conduct into and out of the AV node, providing the substrate for reentry.

Classically, two electrocardiographically distinct forms of AVNRT may occur. In "typical" AV node reentry, antegrade and retrograde conduction occurs over the slow and fast AV node inputs, respectively; retrograde P waves are obscured by the preceding QRS complex. In the "atypical" form of AV node reentry, the circuit is reversed, resulting in a long RP and short PR with an inverted P wave. Thus typical AVNRT resembles ORT and atypical AVNRT resembles PJRT (see previous section). Like PJRT, atypical AVNRT can also be mistaken for sinus tachycardia, as well as other atrial tachycardias (see next section). AVNRT with 2 : 1 conduction and other complex variations can be defined only with an intracardiac electrophysiologic study.

Primary Atrial Tachycardias

Atrial tachycardias present with diverse electrocardiographic patterns, including discrete and regular P waves (ectopic atrial tachycardia, intraarterial reentry), sawtooth flutter waves (atrial flutter), or disorganized atrial activity (atrial fibrillation, chaotic atrial tachycardia).[9] Conduction to the ventricles can be variable, and the ventricular rate primarily determines the severity of symptoms, though loss of AV synchrony can also be important. When 1 : 1 conduction is present, adenosine or vagal maneuvers producing transient AV block will reveal the faster, ongoing atrial rate. Direct recordings of atrial activity (via esophageal, epicardial, or intraarterial recordings) are also useful, particularly in revealing 2 : 1 AV conduction. Despite the potential electrocardiographic similarities of the various primary atrial tachycardias, the varying mechanisms confer important differences in clinical behavior and management.

Most atrial tachycardias encountered in the pediatric intensive care setting are due to atrial reentry and are commonly referred to as "atrial flutter" regardless of whether the classic saw-toothed pattern (as in neonatal atrial flutter) is observed. In older patients with congenital heart disease (CHD), the term *intraatrial reentrant tachycardia* (IART) is often used to describe the slower, scar-dependent atrial reentry, which can result in normal-appearing P waves (rather than classic "flutter" waves). Because of the slower atrial rate, 1 : 1 AV conduction may be especially common, further confounding the diagnosis. Likewise, administration of an AV node–

blocking agent may result in 2 : 1 AV conduction, leading to the erroneous conclusion that the tachycardia has been converted to sinus rhythm with first-degree AV block. Thus this arrhythmia should be suspected in any patient with postoperative CHD presenting with a monotonous and inappropriate tachycardia, otherwise suggestive of sinus tachycardia on ECG.

Atrial fibrillation, a common arrhythmia among the elderly, is far less common in pediatric patients. It may occur as the result of atrial myocarditis,[10] secondary to an underlying reentrant SVT[11] or mechanical stimulation by central venous catheters (Fig. 35.3). In patients with WPW syndrome, rapid conduction over the accessory pathway during atrial fibrillation can be life-threatening. When atrial fibrillation occurs in a young patient, the underlying basis should be sought because the long-term implications and treatment measures are much different than in adult patients.

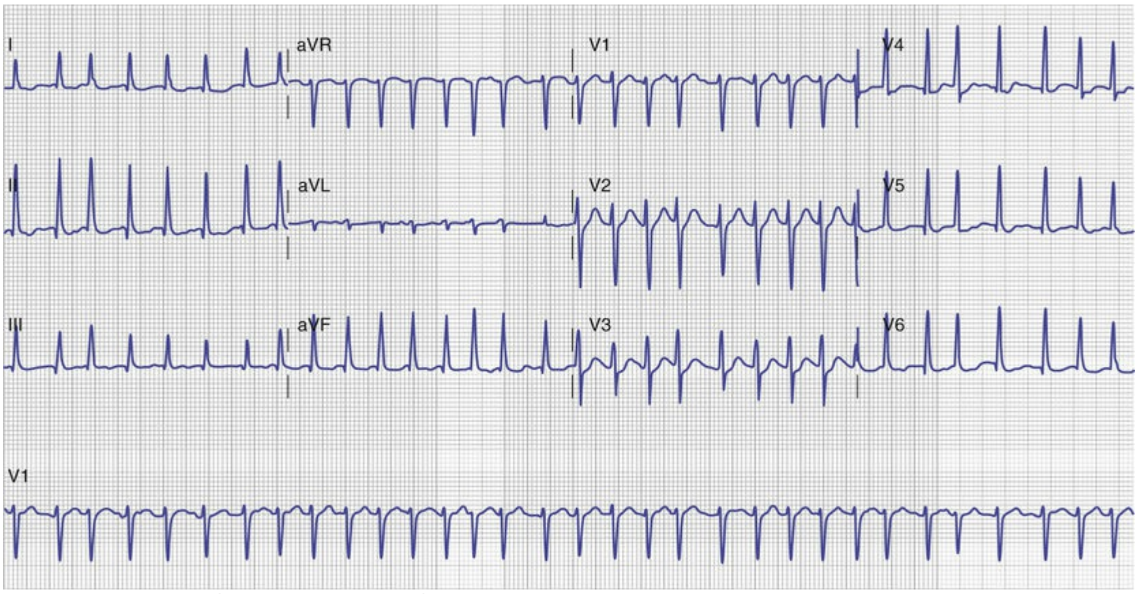

FIG. 35.3 Sustained atrial fibrillation in a previously healthy 17-year-old placed on extracorporeal membrane oxygenation for pneumonia and acute respiratory distress syndrome. Review of stored telemetry revealed atrial ectopy soon after cannulation, eventually initiating atrial fibrillation. Following direct current cardioversion to sinus rhythm, frequent ectopy persisted until the venous cannula was repositioned. Several months later, the patient remained free of further arrhythmias.

Ectopic atrial tachycardia (EAT) is an automatic arrhythmia that typically presents as an incessant and chronically elevated atrial rhythm that may be mistaken for sinus tachycardia, especially when the automatic focus is in the right atrium. First-degree AV block may be seen as a physiologic response to the inappropriately accelerated rate. Patients with EAT usually experience no overt palpitations but present instead with ventricular dysfunction and sometimes frank congestive heart failure (CHF). Because adenosine may transiently inhibit the automatic focus, termination with adenosine is nondiagnostic in distinguishing EAT from sinus tachycardia.

Instead, careful scrutiny of the P wave morphology, especially with transitions between the EAT and sinus, is necessary to establish the diagnosis.

Chaotic atrial tachycardia is an uncommon arrhythmia that is usually observed in infants and toddlers, often in association with a viral respiratory illness.[12] The hallmark features are a rapid and irregular atrial rate, often exceeding 300 bpm, and presence of multiple P-wave morphologies. The resulting ventricular response is irregularly irregular, simulating atrial fibrillation. However, this rhythm is probably the result of multiple triggered foci within the atria, and thus acute termination measures (ie, direct current cardioversion, adenosine, or pacing) are of little benefit. Usually this arrhythmia resolves within weeks or months of presentation. Treatment is based on the severity of symptoms.

Junctional Ectopic Tachycardia

Junctional ectopic tachycardia (JET) probably arises from an abnormal automatic focus or a protected microreentrant circuit in the region of the AV node or proximal His bundle. Antegrade conduction is usually over the normal His-Purkinje system with a narrow QRS. Retrograde (ventriculoatrial [VA]) block with complete VA dissociation and "sinus capture" complexes aid in the recognition of this mechanism. Sometimes AV block coexists with JET. Variants include the common transient postsurgical JET, a congenital chronic JET, and paroxysmal JET described primarily in adults.[13,14] As in postoperative atrial tachycardias, direct atrial recordings aid the diagnosis. In some cases, JET is associated with 1 : 1 VA conduction, in which case additional pacing or pharmacologic maneuvers are necessary to distinguish it from other mechanisms of SVT.

Ventricular Tachycardias

VTs arise exclusively within the ventricle(s), and, by definition, the QRS duration is always aberrant and prolonged for a given age and heart rate. The QRS morphology may be either uniform or changing (bidirectional, polymorphic). Classically, VTs are associated with VA dissociation (atrial rhythm at a slower rate). Thus VA dissociation, when present, is helpful, but when it is absent (or uncertain) it does not exclude VT as the underlying mechanism. The presence of periodic fusion complexes (QRS morphology intermediate between tachycardia morphology and sinus morphology) is diagnostic. However, in infants and young children, ventricular tachycardia may be mistaken as SVT due to the relatively narrower QRS complexes and 1 : 1 VA conduction. JET with aberrancy is characterized by sinus capture complexes (or sustained AV conduction during atrial pacing) without change in QRS.

Like SVTs, VTs are diverse in pattern, mechanism, and severity, and they may result from each of the tachycardia mechanisms (reentry, automaticity, and triggered activity) with important therapeutic implications. The clinical setting, electrocardiographic pattern, and severity of symptoms dictate acute treatment approaches.

Approach to Diagnosis

Monitoring and General Assessment

In the intensive care setting, there may be a tradeoff between precision of diagnosis

and urgency of therapy. Even so, appropriate diagnosis remains key to establishing appropriate ongoing therapy. When an arrhythmia develops, factors such as level of consciousness, ventilation, tissue perfusion, and acid-base status (including mixed venous saturation and lactate) govern what diagnostic measures can be employed before acute therapy. Minimal initial diagnostic evaluation should always include permanently recorded ECG rhythm strips, along with a rapid review of drugs being administered, potential toxic exposures, respiratory and acid-base status, and known associated illnesses that might be arrhythmogenic. Electrolytes, including calcium and magnesium, should be obtained along with drug screening in the patient presenting with altered mental status. The history of surgical procedures for CHD and trauma (chest and cranial) should be quickly reviewed. Indwelling catheter position should be noted on radiographs for potential intracardiac location. Concurrent with this brief survey, a differential diagnosis of the rhythm disturbance should be established quickly, followed by the most appropriate emergency therapy. If the patient is sufficiently stable, therapy may be deferred until a 12-lead ECG is obtained and other diagnostic measures taken for more precisely characterization.

Surface Electrocardiogram

The surface ECG remains the cornerstone of arrhythmia diagnosis. Certainly in patients with known cardiac abnormalities, and arguably in all patients admitted to the ICU, a baseline ECG should be obtained at admission. This ECG may provide a valuable baseline for later comparison in the event of a new arrhythmia. Because these arrhythmias occur in a monitored environment, a strip should be available to assess the rate, regularity, QRS morphology and duration, and AV relationship (Table 35.2), which should provide an initial differential diagnosis (Fig. 35.4). Ideally, multiple leads should be inspected. For sustained tachycardias, a full 12-lead ECG should be obtained whenever possible because diagnostic details, such as QRS aberrancy, atrial rate, and P-wave morphology, or hidden features, such as "flutter waves," may be evident only in selected leads (Fig. 35.5). Rate trends should be reviewed for abruptness of onset to help discriminate between sinus and nonsinus tachycardias in the critical patient.

TABLE 35.2

Electrocardiographic Patterns

Pattern	Description
AV Block	
Mobitz I	Shortened PR of first conducted beat after block
Mobitz II	No change in PR before/after block
	Periods of high-grade block
Third-degree	Fixed, rather than variable, RR interval
Supraventricular Tachycardias	
AV reentrant supraventricular tachycardia	P waves obscured or buried in ST segment
AV nodal reentrant supraventricular tachycardia	P waves obscured by terminal QRS
	"Pseudo" R′ in lead V_1 during tachycardia, not sinus
Junctional ectopic tachycardia	Narrow QRS tachycardia, VA dissociation
	RR periodically shortened because of sinus capture complexes[a]
Atrial ectopic tachycardia	Monotonous rate, inappropriately fast
	Abnormal P-wave morphology (may be subtle)
Intraatrial reentrant tachycardia	Inappropriately fast rate, discrete P waves, variable AV conduction in postoperative patient with congenital heart disease

Atrial flutter	Variable RR interval
	Rapid, sawtooth flutter waves (>280 beats/min)
Atrial fibrillation	Irregular ventricular rate
	Coarse baseline with no discernible P waves
Chaotic atrial tachycardia	≥3 P-wave morphologies, irregular atrial rate, variable AV conduction (periods or atrial flutter or fibrillation common)
Ventricular Tachycardias	
Monomorphic	Wide QRS for age, different from baseline
	Slurred upstroke of QRS
	Variable VA conduction[b]
	Sinus capture complexes[b]
Idiopathic types	Left bundle branch block, inferior axis (right ventricular outflow tract origin)
	Right bundle branch block, left superior axis (left ventricular septal origin)
Bidirectional	Alternating QRS axis (beat-to-beat)
Torsades des pointes	Initiation with "short-long-short" sequence
	QT-interval prolongation before onset
	"Twisting" of QRS axis

[a]Junctional ectopic tachycardia may be associated with third-degree AV block.

[b]Helpful when seen; absent if 1 : 1 VA relationship.

AV, atrioventricular; *VA*, ventriculoatrial.

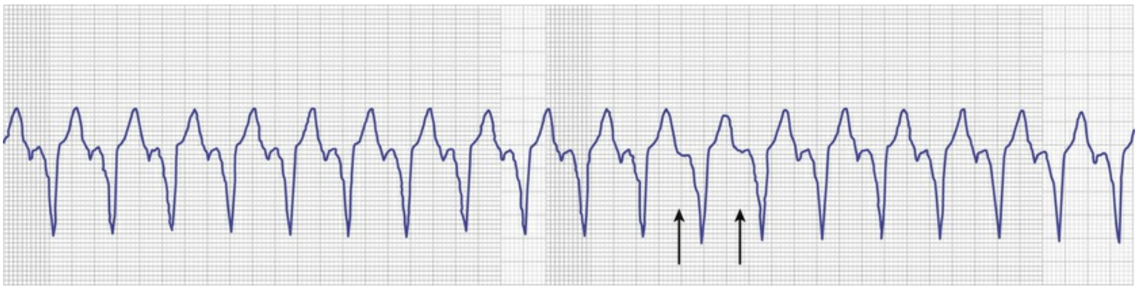

FIG. 35.4 Ventricular tachycardia in an 8-year-old with previous muscular ventricular septal defect repair. Note transient ventriculoatrial block *(arrows)*, excluding a supraventricular mechanism with aberrant conduction.

FIG. 35.5 Ventricular tachycardia following cardiac surgery. Note similarity between QRS complexes during sinus rhythm and ventricular tachycardia in two of three recorded leads.

While the surface ECG usually is sufficient to characterize bradycardias, additional diagnostic maneuvers, sometimes coupled with direct recording of atrial activity, may be required to accurately characterize tachycardias. Changes in ventricular rate and regularity, QRS duration and morphology, and atrial-to-ventricular relationship must be actively sought. When available, temporary atrial

pacing wires or an esophageal ECG can facilitate the diagnosis (Fig. 35.6). Likewise, observing the response of an arrhythmia following perturbations such as PACs or PVCs may be informative. Repetitive patterns in ventricular activation referred to as "grouped beating" always provide important clues to the diagnosis.

FIG. 35.6 (A) Narrow QRS tachycardia in an infant following a stage I Norwood operation. Possible atrioventricular (AV) dissociation is suggested, but P waves are not easily discerned on the surface electrocardiogram. (B) Atrial recording from the same patient (after rate increased) using an epicardial atrial pacing wire. AV dissociation with faster junctional rate is demonstrated, typical of junctional ectopic tachycardia. Absence of clearly shortened RR intervals because of sinus capture might indicate associated AV block.

Bradycardias

Perhaps the most important diagnostic issues in bradycardias are determination of AV conduction and the status of underlying intrinsic escape rhythms. This should usually be straightforward when the atrial rate exceeds the ventricular rate during second-degree or third-degree AV block. In complete AV block, the resultant escape rhythm is usually regular; in second-degree AV block, the ventricular intervals vary (see Fig. 35.1). This is helpful when sinus node disease and AV block coexist where variation of the RR interval implies some degree of AV conduction. When atrial pacing is feasible (as in patients with recent cardiac surgery), AV conduction can be more directly characterized.

The distinction between bradycardia resulting from AV block and sinus nodal dysfunction may have important therapeutic implications. If AV nodal conduction is intact, it is usually most appropriate to pace the atrium only (see AAI mode) rather than perform dual-chamber pacing. In contrast, isolated AV block is best managed by sensing and tracking the intrinsic atrial rate (see DDD mode).

Extrasystoles

Extrasystoles, or premature beats, are defined as supraventricular (supraventricular premature beats or premature atrial complexes) or ventricular (premature ventricular complexes, ventricular premature beats [VPBs]) in origin. True junctional extrasystoles are uncommon. When the extrasystole results in an early QRS with

normal morphology and duration, a supraventricular extrasystole may be presumed. Usually, an early P wave can be discerned, but it may be obscured by the preceding T wave in certain leads. The ensuing sinus beat is usually advanced by the atrial extrasystole, but entrance block can result in a "full compensatory pause," often attributed to a ventricular extrasystole.

Isolated premature QRS complexes with prolonged QRS duration may represent either ventricular extrasystoles or aberrantly conducted atrial extrasystoles. Distinguishing the two may be difficult from a single rhythm strip. Premature P waves often may be obscured in a particular lead, or the ventricular extrasystole morphology may appear similar to the sinus QRS in one lead (but totally dissimilar in another). The ECG features favoring ventricular extrasystoles over aberrantly conducted atrial extrasystoles include (1) wide QRS morphology, (2) a full compensatory pause, (3) presence of fusion beats, and (4) absence of a discernible premature P wave. In the setting of ventricular preexcitation, variable fusion can occur as a result of exaggerated preexcitation with premature atrial depolarizations. As noted earlier, ventricular extrasystoles usually are followed by a full compensatory pause because the sinus node is not reset by the ventricular depolarization. However, an atrial extrasystole may also sometimes fail to reset the sinus node (because of entrance block) or a ventricular extrasystole may occasionally reset the sinus node because of retrograde (VA) conduction to the atrium.

The distinction between atrial and ventricular extrasystoles may be somewhat academic in otherwise asymptomatic individuals because neither generally warrants therapy. However, either might be a harbinger for myocardial irritability and should prompt a search for underlying causes. Occasionally, measures to suppress ectopy may appear to improve cardiac output by "regularizing" filling time in an otherwise tenuous patient. The relative advantages and risks of any such measure, whether achieved with medications or temporary pacing, need to be considered individually.

Tachycardias With Normal QRS

In otherwise healthy infants, children, and adolescents, SVT usually represents AV reentrant tachycardia or AVNRT (Fig. 35.7). Further distinction between these two mechanisms has little impact on acute management. However, in the ICU setting, primary atrial tachycardias (including sinus tachycardia) and junctional tachycardias are more prevalent (particularly following cardiac surgery). The finding of abnormal P-wave morphology (determined by 12-lead ECG), a PR interval greater than 50% of the RR interval, or completely obscured P waves favors a nonsinus mechanism. Finally, ensuring normal QRS duration for age, rather than simply relying on adult standards, is essential in discriminating from VTs.

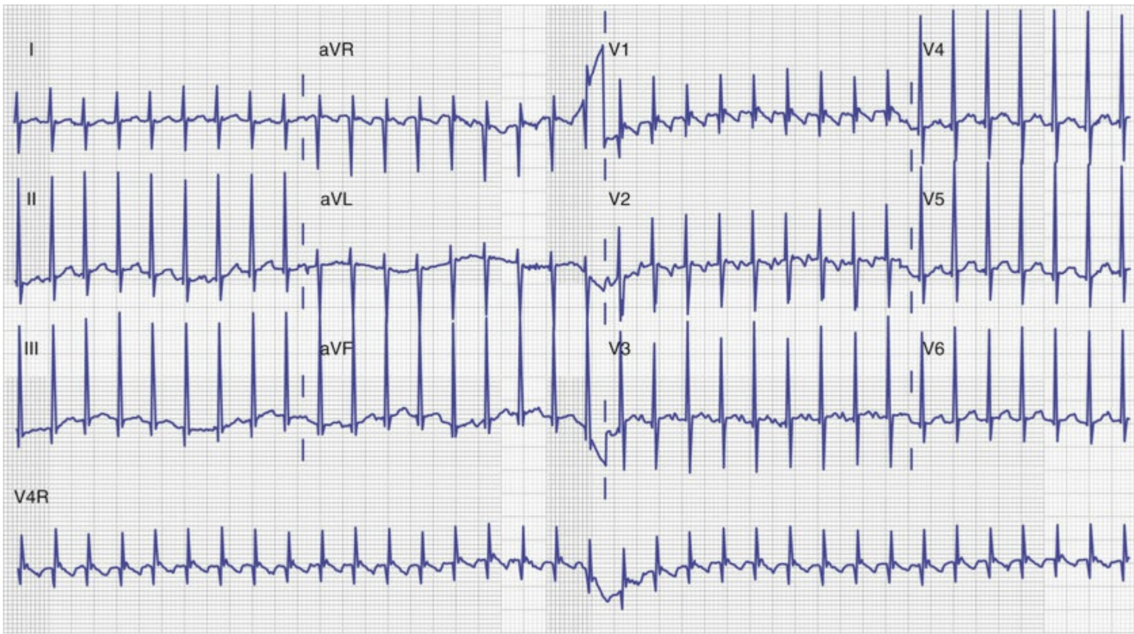

FIG. 35.7 Supraventricular tachycardia resulting from atrioventricular nodal reentry in an infant. Although considerably less common than orthodromic reciprocating tachycardia in this age group, the P wave on the terminal portion of the QRS complex results in a "pseudo rSr′ pattern." During sinus rhythm, this terminal deflection on the QRS was absent, and the transesophageal recording confirmed the mechanism.

Distinguishing sinus tachycardia from various types of SVT may be difficult. In young patients, intraarterial reentry, atrial flutter, and atrial fibrillation are usually seen following surgical treatment for congenital heart defects involving the atrium (atrial septal defects, atrial repair of transposition of the great arteries, or the Fontan operation).[15] The term *intraarterial reentrant tachycardia* (IART) is often used in this setting when discrete P waves are present rather the usual sawtooth "flutter waves." Because the atrial rate is often relatively slow in comparison with "typical" atrial flutter, a high index of suspicion is essential in recognizing this rhythm from sinus rhythm or sinus tachycardia, especially when fixed 1 : 1 conduction or 2 : 1 conduction (with blocked P waves obscured by the QRS or T wave). Again, direct atrial recordings using transesophageal electrocardiography or temporary epicardial atrial pacing wires usually facilitate the diagnosis and characterize the AV relationship (see Fig. 35.6B), as can vagal maneuvers or administration of adenosine to temporally interrupt AV conduction.

Tachycardias With Prolonged QRS

Generally, tachycardias with prolonged QRS should be presumed to be VTs until or unless evidence of an alternative diagnosis is clearly demonstrated. VA dissociation, the hallmark ECG feature of VT, may not be seen in childhood because of rapid retrograde conduction over the AV node (see Fig. 35.4). The distinction between VT and SVT with aberrant conduction can be difficult and may ultimately require invasive electrophysiologic study. Prolonged attempts to differentiate SVT from VT by noninvasive means may simply delay treatment, and the wrong conclusion may prove disastrous: acute treatment based on a presumed diagnosis of VT is rarely deleterious, even when the mechanism subsequently proves to be supraventricular.

However, an erroneous presumption of "SVT with aberrant conduction" may result in rapid clinical deterioration. When feasible, a full 12-lead ECG may aid in the diagnosis, particularly when a baseline ECG in normal rhythm is available for comparison. Apparent hemodynamic stability should not be mistaken as evidence of SVT over VT, whether in an otherwise healthy child or in a patient with known cardiac disease.

Monitoring of Atrial Depolarization

When the AV relationship during a tachycardia is unclear, sometimes it can be inferred indirectly by other available monitoring. Invasive arterial and venous pressure waveforms can help define atrial contractile action in some situations. For example, cannon A waves are commonly noted in patients with atrial flutter or JET.

Direct recording of atrial activity is necessary when the AV relationship cannot be determined from the surface ECG or otherwise inferred by the means described. Patients recovering from cardiac surgery may have temporary atrial epicardial pacing wires that can be used to record atrial electrograms directly while simultaneously recording the surface ECG (see Fig. 35.6B). Attachment of the atrial wires to a unipolar precordial lead ("V lead") on the monitor is an easy way to observe atrial activation. Otherwise, atrial activity can be readily recorded with a bipolar esophageal catheter inserted in the esophagus behind the left atrium.

Diagnostic Uses of Adenosine

Although most widely used as an acute therapy for terminating SVT that involves the AV node, adenosine administration also may yield important diagnostic clues to the underlying arrhythmia mechanism.[16] By producing transient block in the AV node during tachycardia, it is often possible to distinguish AV reentrant tachycardias and AVNRTs (either of which should terminate) from atrial tachycardias and VTs. However, adenosine's effects are not confined to the AV node. Ectopic (automatic) atrial and junctional tachycardias, intraatrial reentry, and certain VTs may also terminate with adenosine. Extreme caution should be taken when administering adenosine during wide QRS tachycardia. Adenosine produces vasodilatation, which theoretically can result in hemodynamic deterioration and tachycardia acceleration, or even fibrillation, if tachycardia fails to terminate. Ventricular fibrillation has been rarely observed when adenosine is administered in the setting of WPW syndrome, probably as a result of atrial fibrillation that is then conducted rapidly to the ventricles. *Cardiac defibrillation capability should always be readily at hand when administering adenosine for diagnostic or therapeutic purposes*.

Treatment of Rhythm Disturbances

The approach to treatment of cardiac arrhythmias is influenced by the clinical setting, but several important considerations help guide therapy in any given situation. The first and most important concern is the degree of hemodynamic compromise associated with a particular arrhythmia. At one extreme, minor rhythm disturbances may be more readily recognized in the intensive care setting than in other situations simply because of the level of monitoring and may prompt undue

attention and unnecessary treatment. At the other extreme, otherwise life-threatening arrhythmias ordinarily requiring acute therapy may be of little acute consequence in the setting of extracorporeal life support (ECLS) or mechanical ventricular assist devices. Indeed, ECLS may serve as adjunctive therapy for refractory arrhythmias. Even ventricular fibrillation in a patient with an LVAD rarely results in immediate decompensation. In contrast, arrhythmias that might ordinarily be well tolerated may be acutely destabilizing in an already critically ill patient and require immediate intervention.

A second important consideration in critically ill patients, particularly those after cardiac surgery, is to favor therapies that maintain appropriate AV synchrony, whenever feasible. In the setting of marginal hemodynamics, the practice of medically slowing the ventricular rate during arrhythmias such as atrial tachycardias and fibrillation, junctional tachycardia, or AV block may be inadequate to preserve cardiac output (see Fig. 35.8).

FIG. 35.8 Junctional ectopic tachycardia with hypotension immediately improved with faster atrial pacing (in this case, resulting in 2 : 1 atrioventricular [AV] block and AV synchrony).

A third consideration in the management of arrhythmias in the ICU is the recognition that many arrhythmias in this setting are iatrogenic. Even minor arrhythmias may herald more serious issues, such as electrolyte disturbances, acidosis, subendocardial ischemia, excessive catecholamine infusions, or increased intracranial pressure. It is important to identify and correct any such underlying causes because therapies directed at the rhythm itself may not protect from more serious rhythm decompensation.

Finally, whenever feasible, acute and short-term measures with limited potential to impair hemodynamics generally should be favored over chronic therapies. Thus nonpharmacologic therapies, such as pacing or cardioversion, or ultra-short-acting drugs, such as adenosine and esmolol, may be preferable to chronic antiarrhythmic therapy. Whether chronic therapy is warranted for a given arrhythmia is determined more by its underlying mechanism, clinical setting, and frequency than by the severity of the arrhythmias encountered in the intensive care setting. Before beginning chronic antiarrhythmic therapy, consultation with a cardiologist versed in the spectrum of arrhythmias seen in childhood is advisable. The impact of acute measures on chronic arrhythmia management becomes increasingly crucial with the emergence of amiodarone use in the ICU and the increasing availability of nonpharmacologic therapies such as radiofrequency catheter ablation and

implantable defibrillators for a broader spectrum of arrhythmias and patient populations.[17-19]

Bradycardia Therapies

Whenever treatment is instituted for a rhythm disturbance, an underlying cause should be sought and corrected. This is especially important for bradycardias that occur in the intensive care setting, where airway compromise and respiratory insufficiency probably are the most common causes of acute bradycardias. Increased intracranial pressure, hypothermia, or iatrogenic causes also may produce bradycardias that require specific interventions beyond those outlined here. Emergency interventions for AV nodal and sinus nodal dysfunction are essentially identical. Chest compressions should be administered if there is no effective underlying rhythm.

Pharmacologic Treatment of Bradycardias

After appropriate confirmation or restoration of airway integrity and ventilatory function, initial treatment of symptomatic bradycardias is usually pharmacologic, whether the cause is sinus node slowing or AV nodal block. Atropine (0.01–0.04 mg/kg IV or, if necessary, IM or via endotracheal tube) may transiently ameliorate bradycardia caused by hypoxia (or other vagal stimulants), digoxin, intracranial hypertension, or AV block as a result of Lyme disease. Atropine is less likely to reverse bradycardic effects of β-blocking agents or other antiarrhythmic drugs, particularly in the setting of underlying sinus node disease. Epinephrine (0.1 μg/kg) can be administered by various routes to accelerate the heart rate. Continuous infusions of epinephrine (0.05–0.5 μg/kg/min) or isoproterenol (0.02–0.2 μg/kg/min) may be instituted. In general, high-dose epinephrine or isoproterenol infusions should be replaced by temporary pacing as soon as feasible. Even if lower doses of these agents prove adequate, temporary pacing should be available as a backup. Occasionally, methylxanthines are useful as an alternative to pacing for nonlethal bradycardias. Glycopyrrolate and ketamine may help augment rates in bradycardic patients, requiring sedation or anesthesia.

Temporary and Permanent Pacing for Bradycardias

Pacing is an essential adjunct to medical management of arrhythmias in the ICU. Several reviews of pacing in children are available.[20,21] Pacing can be accomplished using permanently implanted pacemaker and lead systems, temporary epicardial leads attached to the heart at the time of cardiac surgery, transvenous placement of a pacing lead, or transcutaneous patches. Most pacing is performed for bradyarrhythmias, although temporary pacing may be used to terminate reentrant tachyarrhythmias.

Principles of Pacing

All pacing requires a complete circuit with at least one lead on or near each chamber that is to be paced. Often, two leads are placed on each chamber (bipolar leads), although sometimes only the cathode is attached to the heart (unipolar leads), with a subcutaneous electrode acting as the anode. The metal can of a permanent

pacemaker can also serve as the anode. The intensity of the pacing stimulus is related to the stimulus duration (pulse width) and its amplitude, which can be expressed as either current (mA) or voltage (V). Energy is proportional to the pulse width and the square of the amplitude. Most temporary pacemakers provide a fixed pulse width, with an adjustable current output (mA). Permanent pacemakers generally have both an adjustable pulse width and amplitude.

Sensing intrinsic activity of the chamber being paced is important to prevent asynchronous pacing that can induce inadvertent tachycardias. The sensitivity of permanent and temporary pacemakers is adjustable. The sensitivity setting (mV) actually refers to a sensing threshold for detection of spontaneous cardiac activity. The spontaneous activity must exceed that threshold to be detected. Thus a lower numeric sensitivity setting makes the pacemaker more sensitive to both spontaneous activity of the atrium or ventricle (appropriate sensing) and other electrical signals (oversensing).

The programmed mode and timing circuits of the pacemaker determine when the pacemaker fires and its response to sensed events. A simplified pacing code uses three letters to describe pacing modes.[22] The first two letters refer to the chamber(s) paced and chamber(s) sensed, respectively (A, atrium; V, ventricle; D, dual). The third letter refers to the response to sensed events (I, inhibit; T, trigger; D, dual). Thus a single-chamber atrial or ventricular pacing demand mode is AAI or VVI mode, whereas dual-chamber pacing is generally DDD mode. Corresponding asynchronous modes are AOO, VOO, or DOO and may be important to prevent inadvertent inhibition of pacing due to electrical interference, such as with electrocautery. Other pacing modes may be employed with permanent pacing systems, and recognizing the peculiarities of these modes is important when distinguishing observed pacing behaviors as appropriate or dysfunctional. Timing intervals most readily adjusted include low rate, AV delay, upper tracking rate (UTR), and postventricular atrial refractory period (PVARP). The sum of the AV delay and the PVARP in milliseconds determines the minimum atrial cycle length (60,000 divided by heart rate) and thus the maximum rate, which can be tracked and paced in the ventricle (UTR).

Temporary Pacing

In the pediatric ICU, temporary pacing is most commonly used in patients after surgical treatment of CHD. Temporary epicardial pacing wires are usually placed on the atria and ventricles, allowing pacing of either chamber. As previously noted, direct atrial recording (by attaching the wire to an ECG lead) may also aid in the diagnosis of tachyarrhythmias. Atrial burst pacing can be used to terminate reentrant supraventricular arrhythmias such as IART, AVNRT, and ORT. Pace termination of ORT is shown in Fig. 35.9. Although JET generally cannot be terminated with burst pacing, atrial pacing at a rate faster than the JET rate often improves hemodynamics by allowing AV synchrony until the JET resolves or is pharmacologically controlled (see Fig. 35.8).

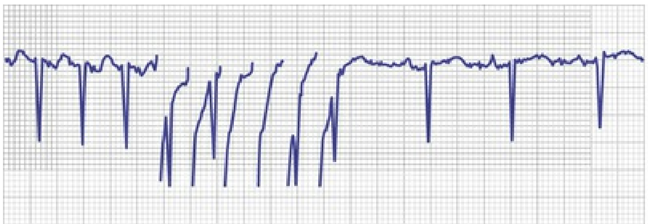

FIG. 35.9 Pace termination of orthodromic reciprocating tachycardia with a burst of atrial pacing.

In bradycardic patients who do not have temporary epicardial pacing wires, transcutaneous pacing can be performed acutely. It is important that electrodes and output are appropriate for the patient size, and positioning may be critical to maintaining capture. In general, transcutaneous pacing is used only for a short time while a temporary transvenous pacing lead is placed. At the bedside, placement of a balloon-tipped temporary transvenous lead is best accomplished via the internal jugular or subclavian vein because the catheter often can be directed to the ventricle "blindly." When fluoroscopy is available, a temporary active fixation may be preferred, allowing more secure positioning and the choice of pacing the atrium, ventricle, or both (in dual-chamber mode).

Setting Temporary Pacing Parameters

For AAI or VVI demand pacing, the pacemaker is usually initially set at a rate higher than the patient's intrinsic atrial or ventricular rate. The pacing threshold (lowest output that captures the chamber being paced) should be determined by decreasing the pacing current (mA) just until capture is lost and then setting output to twice threshold. Similarly, sensing threshold is determined by first lowering to a rate below the intrinsic rate of the chamber being paced, then adjusting the sensitivity to a higher numeric settings (less sensitive) until the pacemaker stops sensing the intrinsic activity as indicated by blinking markers on the device and/or inappropriate pacing on the monitor. The sensitivity is then reduced to a lower numeric value (more sensitive) to determine the highest numeric value at which the pacemaker senses appropriately (sensing threshold). Ideally, the sensitivity is programmed to one-half the sensing threshold, but this is not always possible, especially for temporary atrial leads. Failure to sense can result in inappropriate pacing, which can induce tachyarrhythmias. Fig. 35.10 shows a single inappropriate atrial stimulus initiating sustained ORT.

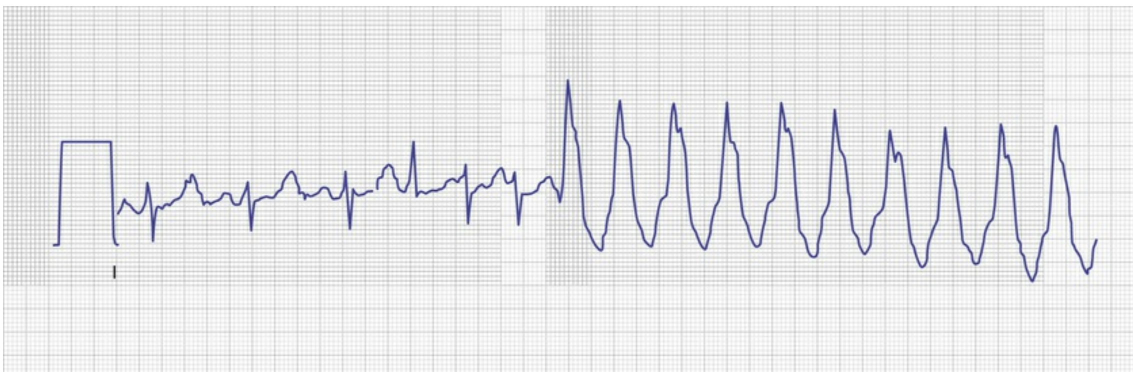

FIG. 35.10 Initiation of orthodromic reciprocating tachycardia with a single atrial paced beat that falls at a vulnerable time. After several narrow-complex beats, bundle branch block in tachycardia results in a wide-complex rhythm.

Dual-chamber pacing is more complex. The atrial and ventricular sensitivity and output are set using basically the same process described for single-chamber pacing. The other timing parameters discussed earlier must also be set, including the upper tracking rate (UTR), the AV delay, and (PVARP). Atrial events occurring during the PVARP will be ignored by the pacemaker and will not result in a ventricular paced event. The pacemaker is also refractory to spontaneous atrial events during the AV interval. Thus the total atrial refractory period (TARP) includes both the AV interval and the PVARP and limits the upper tracking rate (UTR cannot exceed the TARP). Thus increasing the UTR often requires shortening the AV interval and/or the PVARP, thus decreasing the TARP.

The TARP also determines high-rate behavior when atrial rates exceed the UTR. If the spontaneous atrial cycle length (60,000 ms/min divided by the spontaneous atrial rate in bpm) is less than the TARP, only half of the spontaneous atrial beats will result in pacing. The point at which this occurs is known as the “2 : 1 block rate.” In contrast, if the intrinsic atrial cycle length is greater than the sum of the AV delay and PVARP, atrial events exceeding the UTR will still be noted by the pacemaker. The resulting pattern of ventricular pacing resembles Wenckebach AV conduction and is referred to as “pacemaker Wenckebach.” Thus it is desirable to program the AV delay and PVARP such that the resulting sum (TARP) is less than the upper tracking limit in milliseconds (60,000 divided by upper programmed rate) to favor pacemaker Wenckebach behavior and avoid acute drop in pacing rate by 50% when the UTR is reached. However, it is also important to distinguish appropriate pacemaker Wenckebach from failure to sense the atrium or failure to pace the ventricle. Fig. 35.11 shows 1 : 1 conduction, 2 : 1 block, and pacemaker Wenckebach at different pacemaker settings in a patient with a dual-chamber pacemaker for high-grade AV block.

FIG. 35.11 Examples of pacemaker high-rate behavior. Each panel shows a surface electrocardiogram with the simultaneous atrial electrogram below. *Top,* 1 : 1 Atrioventricular conduction. Each sensed atrial event falls outside the total atrial refractory period, resulting in a corresponding paced ventricular event. *Middle,* 2 : 1 Block occurs when the total atrial refractory period exceeds the spontaneous atrial cycle length. Every other atrial beat falls within the refractory period and fails to trigger a ventricular pacing stimulus. *Bottom,* "Pacemaker Wenckebach" operation occurs when the atrial rate reaches the upper tracking rate. Gradual lengthening of the atrioventricular delay ensures that the ventricular pacing does not occur above the upper tracking rate. Eventually, an atrial sensed event falls within the refractory period so that a ventricular pacing stimulus is not triggered. All three recordings were obtained in the same patient over a short period by adjusting the programmable pacemaker parameters. (From Sliz NB Jr, Johns JA. Cardiac pacing in infants and children. Cardiol Rev. 2000;8:223-239.)

When initiating dual-chamber pacing, it is important to be sure that the atrial lead senses appropriately and that the rates, intervals, and refractory periods are set appropriately to allow the pacemaker to track the spontaneous atrial rate. If the intrinsic atrial activity is not appropriately sensed and the dual-chamber temporary pacemaker's low rate is lower than the patient's intrinsic atrial rate, you may falsely assume that dual-chamber pacing is occurring when it is not. The presence of cannon

A waves on the central venous pressure tracing may provide a clue that AV synchrony is not occurring. Reversing the atrial leads, lowering the numeric atrial sensitivity, or adjusting the AV interval, UTR, or PVARP may remedy this situation. If the atrium still cannot be sensed appropriately, setting the pacemaker's low rate higher than the patient's own atrial rate will allow AV synchrony. In effect, this is pacing in DVI mode: pacing atrium and ventricle, sensing the ventricle, and inhibiting pacemaker output when spontaneous ventricular beats occur, avoiding asynchronous pacing by maintaining a higher atrial-paced rate.

Occasionally, a reentrant arrhythmia known as *pacemaker-mediated tachycardia* (PMT) may be seen, in which a DDD pacemaker (temporary or permanent) senses the atrium and paces the ventricle, with the patient's own AV node conducting the impulse up from the ventricle to the atrium and the cycle repeating again. Thus the pacemaker acts as the antegrade limb of the reentrant circuit, while the patient's own AV node acts as the retrograde limb. Usually, PMT can be avoided with careful adjustment of the pacemaker's AV interval and PVARP. In a permanent pacing system, PMT can usually be terminated acutely by placing a magnet over the pacemaker; the resultant asynchronous pacing effectively interrupts the antegrade limb of the reentrant circuit. Fig. 35.12 shows initiation of PMT by loss of atrial capture with termination of the tachycardia by a spontaneous ventricular beat.

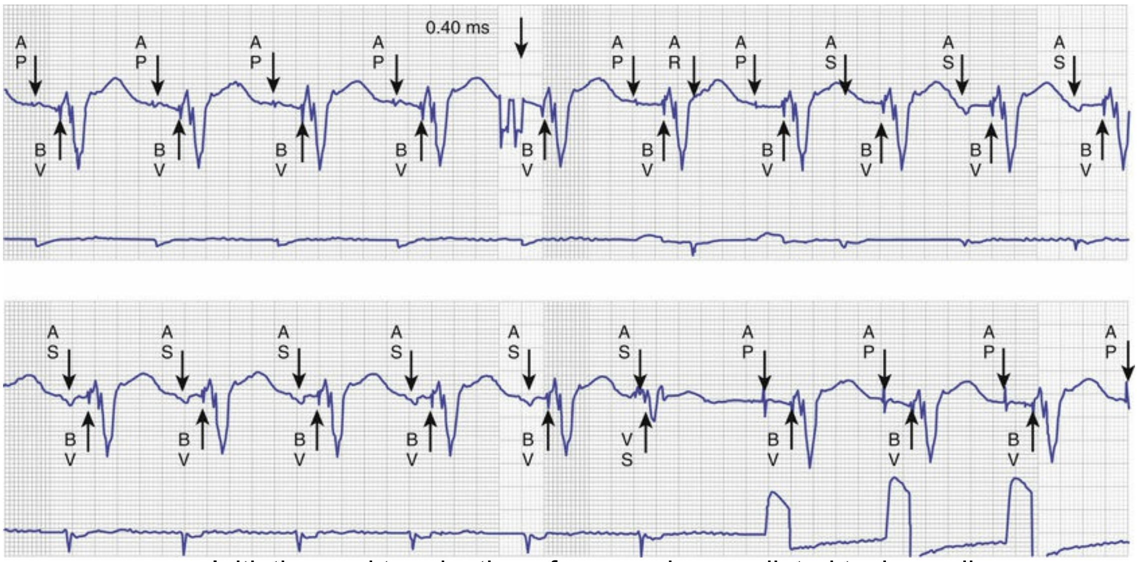

FIG. 35.12 Initiation and termination of pacemaker-mediated tachycardia. *Top,* Two atrial pacing stimuli fail to capture, followed by ventriculoatrial conduction of a ventricular paced beat. The resulting atrial beat *(AS)* is sensed and triggers another ventricular beat, and the process repeats. Had the retrograde atrial beat occurred during the postventricular atrial refractory period, it would not have triggered a ventricular paced beat. *Bottom,* Spontaneous ventricular beat inhibits the ventricular pacing, terminating the process. Atrial electrogram tracings are shown at the bottom of each panel. *AP,* atrial pace; *AR,* atrial refractory; *BV,* biventricular pace; *VS,* ventricular sense.

The selection of optimal temporary pacing mode and rate must be individualized for each patient. Usually atrial pacing (AAI) is preferred over dual-chamber pacing when AV conduction is intact. However, marked first-degree AV block may

unfavorably affect ventricular filling such that dual-chamber pacing provides better hemodynamics. Periodic reassessment of pacing and sensing thresholds, as well as underlying rhythm, should be performed at least twice daily, and hemodynamic responses to changes in mode or timing parameters should be performed as needed with changes in clinical status.

Permanent Pacing

The two most common indications for permanent pacing are high-grade AV block and sinus node dysfunction. AV block may be congenital or acquired, with surgical damage to the conduction system the most common cause of acquired AV block. In patients with surgical AV block, there may be recovery of normal conduction with resolution of edema. In general, permanent pacing is not recommended unless there has been no recovery for 7 to 14 days.[23] Occasionally, if the surgeon is confident that the conduction system has been permanently damaged or if temporary pacing is not reliable, permanent pacemakers may be implanted before 7 days after the initial injury. Elective pacing for congenital AV block in the first decade of life is usually prompted by symptoms, low ventricular rates, or ventricular ectopy. Elective pacing is commonly recommended in the second decade of life even for asymptomatic patients with congenital heart block on the basis of studies showing that the first symptom in teenagers and adults may be catastrophic.[24] Pacing for sinus node dysfunction is most commonly performed in patients with structural heart disease, usually following extensive atrial surgery such as Fontan operation or atrial repair of transposition of the great arteries.

In older children and adults, transvenous pacing is preferred to lower morbidity of implantation, optimize lead placement, and lower susceptibility to lead fractures as compared with epicardial leads, unless intracardiac shunting is present. In younger children, however, concern about venous occlusion in a patient who will require many decades of pacing often favors placement of epicardial pacemaker leads. The development of epicardial leads that elute a small amount of dexamethasone appears to improve epicardial lead performance,[25] although epicardial lead fractures remain a problem that is cause for concern. In patients requiring a lifetime of pacing, various approaches to allow atrial and ventricular pacing are commonly needed (Fig. 35.13). The recent development of “leadless” pacemakers represents an exciting prospect for future pacing options, but in their current design, they are not suitable for younger patients.[26]

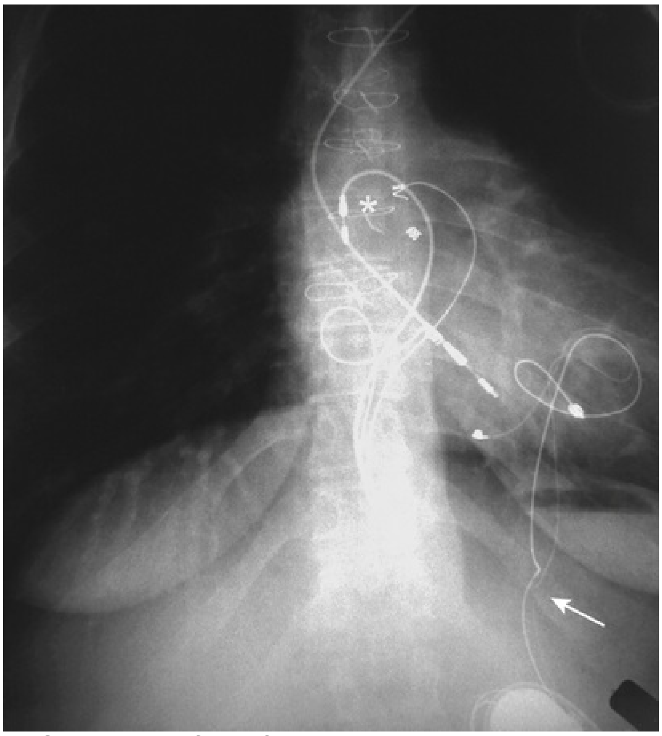

FIG. 35.13 Chest x-ray film of a patient with many abandoned pacing leads. There is a bipolar transvenous lead with the tip in the right ventricle. Another bipolar transvenous lead has been used as an epicardial atrial lead *(asterisk)*. There are two screw-in epicardial leads, one atrial and one ventricular. The atrial lead has a fractured electrode. Two other types of epicardial leads are more toward the apex, one of which is fractured *(arrow)*, and the other of which is kinked. Only the kinked lead is functional. (From Sliz NB Jr, Johns JA. Cardiac pacing in infants and children. Cardiol Rev. 2000;8:223-239.)

Newer Indications for Pacing

Considerable data have shown that a prolonged QRS duration (either due to conduction delay or chronic pacing) results in mechanical dyssynchrony, which further impairs ventricular function. Biventricular pacing, with independent stimulation of the right and left ventricles, can reverse this dyssynchrony and improve ventricular function in some patients. Limited large-scale data are available in the pediatric population on this approach to heart failure treatment (often referred to as cardiac resynchronization therapy), but small studies suggest benefit.[27] Certainly, if pacing is otherwise required in a patient with impaired ventricular function, a biventricular pacing system should be considered. Alternatively, with epicardial pacing, placement of the ventricular lead on the LV apex rather than RV may achieve similar benefit. However, identifying patients most likely to benefit from this modality and the best technique for optimizing the timing of activation between the ventricles remains unresolved. Ventricular pacing to intentionally introduce mechanical dyssynchrony has also been employed in patients with hypertrophic cardiomyopathy, though long-term benefit is probably limited.[28]

Tachycardia Therapies

Vagal Maneuvers

"Vagal maneuvers" were once the most commonly used intervention for terminating SVTs. They occasionally terminate VTs as well. Mechanical maneuvers such as the Valsalva maneuver or carotid sinus massage usually produce effective vagal stimulation beyond infancy. In infants, a similar reflex vagal response can sometimes be elicited by applying firm, steady abdominal pressure or by applying an ice pack to the face. These maneuvers should be attempted for 15 to 30 seconds. Endotracheal suctioning may also terminate tachycardias by this mechanism.

Acute Pharmacologic Therapies

Adenosine

An endogenous nucleoside with profound effects on SA node and AV node conduction, adenosine has become a mainstay in the acute treatment of SVT with normal QRS duration.[16] Administered as a rapid bolus, it produces transient but profound depression of AV nodal conduction and should reliably terminate reciprocating tachycardias (AV nodal reentry, AV reentry). Given the prevalence of AV reentry and AV nodal reentry among otherwise healthy young patients, adenosine is often advocated for wide QRS tachycardias as a therapeutic and/or diagnostic maneuver. It usually causes transient AV block without terminating most primary atrial tachycardias but may transiently suppress atrial automatic tachycardias (ectopic atrial or junctional) and occasionally may terminate atrial reentrant tachycardias. Certain VTs may be adenosine sensitive, particularly those originating because of abnormal triggering in the right ventricular outflow tract.

Adenosine (100–300 μg/kg) must be administered rapidly because of rapid metabolism by erythrocytes. If tachycardia is not terminated, determination must be made regarding whether a larger dose is warranted, the dose was given too slowly, or VA or AV conduction was altered without terminating tachycardia (see discussion on diagnosis). Therefore it is important to record an ECG strip during adenosine administration so that important diagnostic or therapeutic clues are not missed. Because of its brief effect (a half-life of 8–10 seconds), tachycardias sometimes immediately reinitiate following successful termination. If they reinitiate, readministration of the same dose should be attempted rather than increasing the dose further.

In addition to effects on the AV node, adenosine can produce sinus arrest, which may be prolonged in the setting of intrinsic SA nodal dysfunction after heart transplant; in the presence of drugs that interfere with its metabolism, such as dipyridamole and diazepam; or with drugs that may exaggerate its effects, such as class I, II, or III antiarrhythmic drugs. High doses should not be used indiscriminately in these situations. The use of adenosine in patients with reactive airway disease may be problematic because adenosine occasionally triggers severe bronchospasm. Conversely, its effects may be antagonized by aminophylline and other methylxanthines the patient may be receiving.

Adenosine produces dramatic but transient chest pain, along with systemic vasodilatation, both of which tend to increase sympathetic tone. As a result, adenosine may paradoxically accelerate tachycardias if termination is unsuccessful or, in the case of primary atrial tachycardias (atrial flutter or fibrillation), may

produce more rapid conduction over the AV node (after initially slowing the ventricular rate). Various secondary arrhythmias may occur following administration of adenosine, particularly ventricular ectopy, atrial fibrillation, or, rarely, ventricular fibrillation. Although these effects are usually transient, *emergency external cardioversion should always be available whenever adenosine is administered*. The appropriateness of adenosine has been questioned in patients with known ventricular preexcitation syndromes (WPW syndrome) or suspected VTs. Nevertheless, its thoughtful and careful use remains invaluable for both diagnosis and treatment of many tachycardias.

Antiarrhythmic Agents

The addition of pharmacologic agents following adenosine administration should be guided by the clinical situation, known or suspected tachycardia mechanism, and response to adenosine administration. In some cases (such as in patients with wide QRS tachycardia or in hemodynamically compromised patients), it may be most appropriate to proceed directly to pacing termination or cardioversion if adenosine is unsuccessful in restoring sinus rhythm. In other instances, acute antiarrhythmic drug therapy may be warranted.[29]

The Vaughan Williams classification divides drugs according to their surface ECG effects, which often correlate closely with their cellular electrophysiologic effects: those that block cardiac sodium channels (class I); block β-adrenoreceptors (class II); prolong repolarization (class III); and block calcium channels (class IV). Digoxin and adenosine, which are not included in this classification scheme, exert their primary antiarrhythmic effects on the AV node. Magnesium also has depressant effects on the AV node and suppresses early and late afterdepolarizations (triggered activity). Many of the available drugs manifest properties of more than one class, which contribute collectively to their antiarrhythmic action.[30]

In general, class I drugs (particularly IA and IC) slow conduction in atrial, ventricular, or accessory pathway tissue and class III drugs prolong refractoriness in these same tissues. Class IA drugs usually accomplish both effects. β-Adrenergic antagonists, calcium channel antagonists, digoxin, and adenosine act primarily by slowing AV nodal conduction or inhibiting abnormal automaticity. Thus the latter group of drugs is primarily used for reciprocating tachycardias using the AV node (ART, ORT, AVNRT) or to induce second-degree AV block during a primary atrial tachycardia. In contrast, class IA, IC, and III drugs may be more effective in terminating or directly suppressing primary atrial tachycardias and also may be effective for reciprocating tachycardias.[6,29]

Despite the various antiarrhythmic agents available for chronic therapy, relatively few are suitable for acute administration to the critically ill patient either because the drugs are not available in intravenous formulation or they have significant negative inotropic effects when administered intravenously (Table 35.3). This discussion is limited to agents suitable for acute and short-term parenteral administration.

TABLE 35.3

Treatment of Bradycardias, Supraventricular Tachycardias, and Ventricular Tachycardias

			Long-Term

			Therapies
Bradycardias			
Sinus bradycardia	Atropine 0.01 mg/kg	Temporary pacemaker	Permanent pacemaker (AAIR, DDDR)
	Epinephrine 0.1 mg/kg	Isoproterenol infusion	
	Transcutaneous pacemaker		
AV block (high-grade)	Transcutaneous pacemaker	Temporary pacemaker	Permanent pacemaker (DDDR)
Supraventricular Tachycardias			
Sinus tachycardia	Identify cause(s)	Sedation, pain control	β-Blockers, if chronic
		Adjust catecholamines	Consider nonsinus mechanism
		Respiratory support	
Paroxysmal supraventricular tachycardia, AV nodal reentrant tachycardia	Vagal maneuvers	Esmolol	β-Blockers, class I, class III
	Adenosine	Verapamil	Amiodarone
	Transesophageal termination	Procainamide (IV)	Radiofrequency ablation
	Procainamide	Amiodarone (IV)	Radiofrequency ablation
		Class I, class III	
AET and other incessant supraventricular tachycardia	Amiodarone	β-blockers	
	Esmolol	Amiodarone	
	Avoid cardioversion		
Atrial flutter <24 h	Rate-control (diltiazem IV)	Pace termination	Radiofrequency ablation
	Procainamide	(transesophageal, intracardiac)	Antitachycardia pacemaker
	Pace termination with pacemaker		
	DC cardioversion		
	Ibutilide (transesophageal echocardiography if duration unknown of >24 h to rule out thrombus)		
Atrial fibrillation <24 h	Same as above, except pace termination not feasible)		
Chaotic atrial tachycardia	Procainamide, amiodarone	β-Blocker (rate control)	Propafenone, amiodarone
Ventricular Tachycardias			
Monomorphic (conscious, stable)	Procainamide/lidocaine	Procainamide/lidocaine	Defined by substrate
	DC cardioversion	Amiodarone	
	Pace termination if PM, ICD		
Known heart disease	Same	Amiodarone	ICD, Radiofrequency ablation
			Amiodarone
Known idiopathic	Consider IV verapamil	β-Blocker	Ca-channel blocker
	Avoid cardioversion		β-Blocker
			Radiofrequency ablation
Pulseless (monomorphic, polymorphic)	DC cardioversion	Amiodarone (unless long QT)	ICD
	β-Blocker	β-blocker	
	Amiodarone	Magnesium	
Ventricular fibrillation	Defibrillation	Epinephrine	ICD
		Vasopressin	

AET, atrial ectopic tachycardia; *AV*, atrioventricular; *ICD*, implantable cardioverter-defibrillator; *PM*, pacemaker.

All antiarrhythmic agents have the potential for producing bradycardia, particularly when administered acutely, and most have negative inotropic and/or hypotensive effects. Careful observation is required during initial administration

and subsequent infusion of all IV antiarrhythmic agents. Although many are contraindicated in cases of heart failure or hypotension, therapy may be necessary if the arrhythmia is contributing significantly to the patient's hemodynamic compromise.

Procainamide

Procainamide is useful for various SVTs and VTs in the intensive care setting. Its broad electrophysiologic effects include both conduction slowing and increased refractoriness in atrial tissue, ventricular tissue, and accessory AV connections. Unlike quinidine, procainamide can be administered intravenously. Effective plasma concentrations (6–10 μg/dL) can be readily achieved with a total loading dose of 15 mg/kg over 15 minutes (or in small-bolus increments at a similar rate). Careful and repeated blood pressure monitoring is required because of potential negative inotropic and direct vasodilator effects. If hypotension complicates infusion, administration should be momentarily interrupted until blood pressure returns to normal. In primary atrial tachycardias, a vagolytic effect may increase the ventricular response over the AV node. Occasionally, atrial tachycardia that is conducting 2 : 1 to the ventricle slows sufficiently to allow 1 : 1 conduction, converting a hemodynamically stable rhythm to an unstable rhythm. Thus one should always be prepared to use cardioversion if necessary.

Procainamide, like other class IA and class III drugs, is contraindicated in patients with the congenital or acquired long QT syndromes. Regular monitoring of plasma concentration every 6 to 12 hours is necessary during IV administration to maintain levels between 5 and 10 μg/dL. The active metabolite N-acetylprocainamide contributes to the antiarrhythmic action; higher levels of the parent drug may be necessary in patients lacking the enzyme to produce this metabolite.

Lidocaine

Intravenously administered lidocaine is useful for suppressing and sometimes terminating VTs in children. Although somewhat less likely to acutely terminate VTs than procainamide or amiodarone, lidocaine's lack of significant negative inotropic effect makes it attractive for this indication. The usual loading dose is 1–2 mg/kg acutely or 3 mg/kg over 20 to 30 minutes, followed by a 20–50 μg/kg/min infusion. Lidocaine levels should be monitored to prevent central nervous system (CNS) toxicity. With chronic use (4–7 days), accumulation of the metabolite glycine xylide may impair drug efficacy by interfering with the parent drug effect at the sodium channel. Despite traditional recommendations for its use in ventricular fibrillation, lidocaine actually increases defibrillation energy requirements.

β-Blocking Agents

A limited number of β-blocking agents are useful for intravenous treatment of tachycardias. Acutely, their role is generally limited to incessant tachycardias, which seem to be dependent on sympathetic tone, and VTs related to myocarditis, ischemia/reperfusion injury, or congenital long QT syndromes. In hemodynamically unstable patients, β-blocking agents should be used cautiously because of hypotension and potential sinus bradycardia once tachycardia terminates. All may produce bronchospasm, hypotension, or bradycardia or may depress ventricular

function.

Esmolol, a short-acting, nonselective β-blocker with a half-life of 2 to 5 minutes, can be administered as a continuous infusion. A loading dose of 500 μg/kg is followed by an infusion of 50–100 μg/kg/min. The infusion can be titrated upward by doubling every 3 to 5 minutes up to 500 μg/kg/min. Repeat loading doses may be useful as the infusion is increased. Its very short half-life is excellent for short-term use, but extended efficacy is limited by tachyphylaxis. For longer-term intravenous administration, metoprolol (0.05–0.10 mg/kg) is administered by slow intravenous infusion every 4 to 6 hours, carefully observing for hypotension (or bradycardia).

Amiodarone

Amiodarone is arguably the single-most potent antiarrhythmic drug available, both in the acute, IV setting and when administered chronically. At sufficient doses, it is often effective in controlling various tachycardias refractory to other antiarrhythmic agents.[31] Although typically regarded as a class III agent, its effects are considerably more diverse. It not only prolongs repolarization (by blocking potassium channels), but to varying degrees it blocks some sodium channel (class I effect), calcium channel (class IV effect), and β receptors (class II effect).

Amiodarone is administered as a total loading dose of 5 mg/kg divided into 1-mg/kg aliquots given at 5- to 10-minute intervals. The loading can be truncated if arrhythmia control is achieved. If hypotension ensues, volume expansion or calcium chloride (10–30 mg/kg) should be administered. If arrhythmia control is not achieved, a second loading dose can be administered 30 to 60 minutes later. A continuous infusion of 10 mg/kg over 24 hours can be administered if ongoing therapy is desired.

Calcium Channel–Blocking Agents

Verapamil and diltiazem have proved useful for terminating SVT involving the AV node (AV reentry, AV nodal reentry). However, their acute efficacy is no greater than that of adenosine, and both may cause hypotension or cardiovascular collapse in young infants or patients with poor ventricular function.[32] Either drug can be useful as an alternative to adenosine when tachycardias have repeatedly reinitiated following termination with adenosine.

Both agents may help slow the ventricular response over the AV node during atrial flutter or fibrillation. Verapamil is administered as a bolus of 0.15 mg/kg. Diltiazem can be administered as a bolus of 0.15–0.35 mg/kg and can be infused continuously at 0.05–0.2 mg/kg/hr if ongoing effect is necessary. In addition to vasodilatation and negative inotropic effects, both can accelerate antegrade conduction over accessory pathways in patients with WPW syndrome. Therefore they are contraindicated for preexcited atrial fibrillation, and generally they should not be administered during uncharacterized wide QRS tachycardias. Likewise, oral calcium channel blockers generally should not be used as maintenance therapy for patients with WPW syndrome. If hemodynamic compromise develops, IV calcium gluconate should be administered immediately.

Magnesium Sulfate

Magnesium (administered as 25–50 mg/kg magnesium sulfate) has proved useful in

the treatment of certain ventricular and supraventricular arrhythmias. Its actions appear to be mediated through depression of early and late afterdepolarizations; depressant effects on AV nodal conduction; and, at high doses, indirect inhibition of sodium-potassium adenosine triphosphatase. It is most effective in the acute treatment of torsades de pointes and as a temporizing measure in the treatment of arrhythmias associated with digoxin toxicity.[33] Therapeutic efficacy is not restricted to situations where hypomagnesemia is present. Although magnesium has efficacy comparable with that of adenosine in the acute termination of SVT resulting from AV reentry and AV nodal reentry, it has more severe and lasting adverse effects. It has little demonstrable effect in the acute treatment of monomorphic VTs or polymorphic VTs not associated with QT prolongation.

Digoxin

Digoxin has been used for various supraventricular arrhythmias, including AV reentry, AV nodal reentry, and primary atrial tachycardias. In a randomized controlled trial of infants younger than 4 months of age with SVT, recurrence rates were similar between digoxin and propranolol.[34] Digoxin may increase the risk of rapid antegrade conduction during atrial fibrillation in older patients and possibly infants with preexcitation. Like calcium channel–blocking agents, it should be avoided altogether in the treatment of patients with ventricular preexcitation (WPW syndrome). Its use is further confounded by potentially dangerous interactions with other medications including quinidine, verapamil, amiodarone, flecainide, phenytoin, and warfarin. At toxic dosages, its direct cellular effects may predispose to dangerous tachycardias and bradycardias.

Dexmedetomidine

Dexmedetomidine is a selective α2-adrenergic receptor agonist that provides sedation, anxiolysis, and analgesia with minimal to no respiratory depression. As a result it has become widely used in a variety of settings, including the pediatric ICU. Dexmedetomidine acts as a peripheral parasympathomimetic and a central sympatholytic, with electrophysiologic effects including sinus and atrioventricular node depression.[35] Studies have suggested that dexmedetomidine is effective for acute termination of SVT in children, with fewer side effects compared with adenosine.[36] Serious adverse events including sudden pauses, asystole, and loss of pacemaker capture have also been reported with dexmedetomidine infusion.[37,38]

Cardioversion and Defibrillation

Cardiovascular collapse or failure of mechanical and pharmacologic interventions for tachycardias may warrant cardioversion. For tachycardias with discrete QRS complexes, synchronization with the QRS should be confirmed (the default mode for most defibrillators is nonsynchronized, and most revert to nonsynchronized shocks after each shock is delivered). Proper synchronization may require changing the ECG lead configuration to achieve an upright QRS complex.

Several factors may determine the success of cardioversion and defibrillation. Energy requirements may vary from 0.25 to 1 J/kg for SVTs to greater than 2 J/kg for VTs. Newer defibrillators with a “biphasic” rather than “monophasic” waveform have reduced defibrillation energy requirements. Electrode (paddle) location is an

important variable. If conversion is not achieved with low or moderate energy levels, consideration should be given to changing electrode position before using higher energy levels. Automatic tachycardias are characteristically refractory to cardioversion and may account for treatment failure. Finally, some antiarrhythmic drugs, particularly sodium channel–blocking drugs (see later discussion), increase defibrillation energy requirements and pacing thresholds, whereas other drugs (QT-prolonging drugs) appear to have a favorable effect.[39]

Approach to Therapy

Extrasystoles

In general, isolated extrasystoles do not require treatment unless they are sufficiently frequent to impair hemodynamics or they serve as frequent initiating events for tachycardias. In otherwise healthy children and adolescents, extrasystoles are a benign finding. In other settings, "complex" ventricular extrasystoles may identify patients at increased risk for cardiac arrest. Even in such situations, prophylaxis may not decrease and may actually increase the risk. Effort should instead be directed at identifying possible causes and correcting any predisposing factors, which include ischemia, electrolyte disorders, acidosis, pericarditis, or direct trauma from recent cardiac surgery, blunt or penetrating chest trauma, and intracardiac catheter-induced irritation. Numerous drugs, including digoxin, catecholamines, or drugs associated with the acquired long QT syndrome, may produce extrasystoles.

Sustained Tachycardias

Most sustained tachycardias observed in the intensive care setting warrant immediate attention and intervention. Sinus tachycardia may indicate the need for additional sedation and analgesia or may reflect hemodynamic compromise as a consequence of anemia, hypovolemia, or impaired myocardial function. Sinus tachycardia as a consequence of hyperthermia may be poorly tolerated in children already critically ill, especially following cardiac surgery. Sinus tachycardia may reflect an underlying neuroendocrine process such as hyperthyroidism or pheochromocytoma requiring acute medical intervention (β-blocker) while instituting therapy for the underlying disorder.

Nonsinus tachycardias in patients with primary rhythm disturbances may warrant therapy to prevent life-threatening events, prevent the development of myocardial dysfunction as a consequence of chronic (incessant) tachycardia, or simply alleviate acute tachycardia-related symptoms. The acuity of the situation dictates the approach to therapy. Tachycardias occurring secondary to other abnormalities (structural heart disease, metabolic derangements, drug toxicity) should always be regarded as high risk for serious hemodynamic deterioration.

Unstable Patients

The approach to patients with tachycardia is determined largely by the degree of hemodynamic compromise (see Table 35.3). Patients who are hemodynamically unstable or in cardiovascular collapse resulting from sustained tachycardia almost

always warrant prompt cardioversion or defibrillation. Antiarrhythmic medications (and other supportive measures) should only replace cardioversion in the unstable patient when tachycardia is known to be incessant or is unresponsive to cardioversion (eg, JET, atrial ectopic tachycardia, chaotic tachycardia, and PJRT).

Cardiopulmonary resuscitation should always be instituted in the absence of a pulse or blood pressure, as is typically the case for polymorphic VT and ventricular fibrillation. Although hemodynamic and ventilatory support should be initiated immediately and maintained following tachycardia termination as needed, cardioversion (with bag and mask ventilation initially) should take precedence over other interventions.[40] Underlying factors contributing to the tachycardia should be sought, including hypoxia, infection (cardiac or systemic), drug toxicities (see later), and electrolyte derangements.

Once tachycardia is terminated, acute therapies may focus on either suppressing recurrences or terminating them when they recur. Although antiarrhythmic medications eventually may be necessary to suppress recurrences, most have negative inotropic or vasodilating effects, particularly when administered intravenously. Often it is preferable to delay specific therapy after initial termination until ventricular function improves. Most recurrences of SVTs can be safely treated with temporary pacing or adenosine rather than with repeated cardioversions. In the event of frequent recurrences, a transesophageal catheter may be left in place for this purpose, or a transvenous atrial pacing catheter may be warranted in selected patients. Similarly, temporary ventricular pacing may be useful in some circumstances for recurrent VT. Although adenosine can be administered repeatedly because of its short half-life, the resulting vasodilatation may be poorly tolerated in patients with tachycardia mechanisms unresponsive to adenosine.

Treatment Failure

When seemingly appropriate electrical and pharmacologic interventions fail to terminate tachycardias, three possibilities should be considered: erroneous diagnosis, unrecognized tachycardia reinitiation, or a technical error in the termination technique.

Errors in Diagnosis

As noted previously, automatic atrial tachycardias, JET, and occasionally chaotic atrial tachycardia might be mistaken for tachycardias with reentrant mechanism (ORT, AVNRT, and primary atrial reentry). Each of these conditions is usually refractory to electrical termination (either pace termination or cardioversion), yet the diagnosis may be subtle if atrial activity is obscured.

Confusion between VTs and SVTs with prolonged QRS probably remains the most frequent diagnostic error. Occasionally the presumption of VT may lead to ineffective treatments. For example, following cardiac surgery, incessant, monomorphic wide QRS tachycardia that is refractory to cardioversion may actually be JET with postsurgical bundle branch block. Brief atrial pacing at a faster rate may be necessary to confirm the diagnosis.

Certain tachycardias such as torsades de pointes related to long QT syndromes (congenital or drug-induced) or bidirectional VT resulting from digoxin toxicity must be recognized to provide more appropriate and specific therapies to prevent

recurrences following cardioversion.

Unrecognized Reinitiation

Unrecognized reinitiation may occur following medical termination, pace termination, or cardioversion. In some tachycardias (as in PJRT or other incessant forms of SVT), reinitiation is expected, but it also may occur inadvertently as the result of continued pacing beyond the point of termination or may be facilitated by sinus pauses, junctional beats, or ectopic beats following adenosine or cardioversion. Again, measures to decrease the factors favoring reinitiation (eg, shorter pacing bursts, antibradycardia pacing, and coadministration of an antiarrhythmic drug) should be used rather than further increases in energy or dose of the terminating therapy. With frequent terminations and reinitiation of tachycardia, multiple repeated cardioversions are likely ineffective and may cause myocardial injury.

Improper Technique

Appropriate administration of adenosine is accomplished through an IV catheter (peripheral or central) by rapid push followed immediately with ample flush. Because of rapid metabolism by erythrocytes, arterial administration may be ineffective in terminating tachycardia (yet still produce vasodilatation). Errors in cardioversion or pacing technique are generally attributable to insufficient energy or improper electrode (or paddle) placement. For pace termination, the stimulator must be capable of sufficient output for the pacing modality being used (see section on temporary pacing). Intensive care personnel should be familiar with the defibrillation devices available in the ICU, including adjustment of electrocardiographic gain and lead selection to allow synchronous cardioversion when appropriate. However, in ventricular fibrillation or polymorphic tachycardia, asynchronous countershock is necessary. Use of excessive energy may damage the myocardium and, when repeated, may lead to preterminal bradycardias, which are refractory to all pacing modalities and progress to complete electromechanical dissociation if hypoxia and acidosis are not corrected.

Specific Arrhythmias

Primary Arrhythmias

Some arrhythmias require unique therapeutic approaches or are seen with sufficient frequency to warrant a brief review (Box 35.1).

Box 35.1

Rhythm Disturbances

Primary Rhythm Disturbances

Paroxysmal supraventricular tachycardias (atrioventricular nodal reentrant tachycardia, AVNRT)
- Congenital AV block
- Congenital long QT syndrome, Brugada syndrome
- Other genetic arrhythmias

Ventricular tachycardias resulting from Purkinje hamartoma
Verapamil-sensitive ventricular tachycardias
Accelerated ventricular rhythm

Secondary Rhythm Disturbances

Early Postoperative Arrhythmias

JET
Postsurgical AV block
Early primary atrial tachycardia

Late Postoperative Arrhythmias

Ventricular arrhythmias (postoperative tetralogy of Fallot)
Sick sinus syndrome

Metabolic Derangements

Electrolyte disturbances
Endocrine derangements (thyroid)
CNS injury
Hypothermia, hyperthermia
Acute hypoxia (newborns)
Acute myocardial infarction

Drug Toxicity, Proarrhythmia

Digoxin
Cocaine
Tricyclic antidepressants
Antiarrhythmic drugs
Quinidine/sotalol
Flecainide/encainide
Organophosphates

Infectious

Lyme disease
Myocarditis, endocarditis

CNS, central nervous system; *JET,* junctional ectopic tachycardia.

Orthodromic Reciprocating Tachycardia in Infancy

Infants with ORT can present with tachycardia in utero, at birth, or within the first weeks to months of life. Postnatally, tachycardia sustained beyond a few hours may result in CHF that may progress to shock, acidosis, and complete cardiovascular collapse.[41] In the latter situation, ORT may be terminated during resuscitation efforts such that its causative role remains unrecognized. Thus SVT should be considered in the differential diagnosis of neonatal shock, along with other conditions such as sepsis, aortic coarctation, and congenital adrenal hyperplasia in which sinus tachycardia associated with cardiovascular collapse would be expected.

Tachycardia-Induced Cardiac Dysfunction

Although most SVTs are paroxysmal or episodic, chronic SVTs pose a unique problem. Many are minimally symptomatic and are recognized only by the

inappropriately fast rate. However, with time, varying degrees of CHF become evident and ventricular dysfunction may be severe. Even then, the diagnosis may not be immediately evident. As a consequence, chronic tachycardia must be considered in any patient presenting with gradually progressive CHF. In one series, chronic atrial tachycardia was present in 37% of patients initially diagnosed with "idiopathic" cardiomyopathy and listed for heart transplant.[42]

In patients with structurally normal hearts, the most common incessant SVTs are PJRT and ectopic atrial tachycardia. These conditions may occur throughout infancy, childhood, and adolescence. The rates (often <200 beats/min) and normal PR interval during tachycardia may lead to an erroneous diagnosis of sinus tachycardia secondary to the hemodynamic compromise (see "Approach to Diagnosis" section earlier). An abnormal P-wave axis on 12-lead ECG and Holter monitoring to look for interruptions in the tachycardia with changes in P-wave morphology are helpful. Electrophysiologic study may still be necessary to establish the diagnosis. In infants, incessant VTs and the rare congenital form of JET also are seen.

In each of these entities, it is important first to recognize the primary role of the tachycardia in producing secondary congestive symptoms and to recognize the futility of acute therapies such as adenosine, pace termination, and cardioversion. Most are catecholamine dependent so that inotropic agents may aggravate the situation and compromise the efficacy of antiarrhythmic regimens, whereas β-blocking agents may be useful despite the presence of heart failure. Once the diagnosis is established, chronic antiarrhythmic therapy is instituted to control or limit the tachycardia. Uncontrolled, severe cardiac symptoms may result, but ventricular dysfunction improves once tachycardia is suppressed medically or treated by catheter ablation.[43] Despite the severity of heart failure, antiarrhythmic medications that depress ventricular function are usually well tolerated.

Chaotic Atrial Tachycardia

Chaotic atrial tachycardia is a primary atrial tachycardia characterized by three or more different P-wave morphologies and irregular, rapid atrial rates (Fig. 35.14). Although atrial flutter may be associated with it, episodes are usually self-limited and cardioversion is neither indicated nor effective. Asymptomatic patients with slow or intermittent tachycardia may require no treatment. Occasionally digoxin is used to limit AV conduction when atrial rates are excessive or to enhance contractility in the setting of tachycardia-induced cardiomyopathy.[44] An association with respiratory syncytial virus has been described in some patients.[12] Various agents have been used in symptomatic cases; amiodarone and propafenone are the most effective.[44,45]

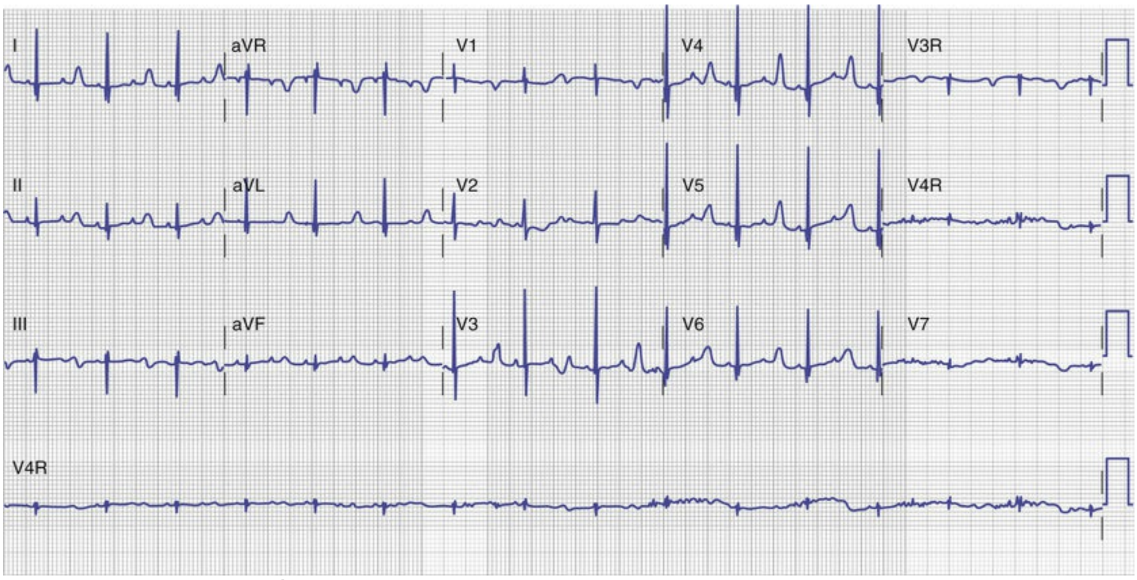

FIG. 35.14 Chaotic atrial tachycardia. Note two discrete P-wave morphologies before conversion to sinus rhythm.

Long QT Syndromes

The long QT syndromes are a diverse group of disorders, both congenital and acquired, in which individuals are at risk for torsades de pointes and sudden death because of abnormalities in ventricular repolarization. In both congenital and acquired forms, the rate-corrected QT intervals usually exceed 0.46 second and, more typically, are greater than 0.48 to 0.50 second. Associated anomalies of T-wave morphology, including T-wave alternans, "bifid" T waves, and prominent U waves, are common. It may be difficult to establish the diagnosis of congenital long QT syndrome because QT prolongation may not be severe, and affected individuals sometimes have a normal QTc.[46] Congenital long QT syndrome should be considered in all patients with QT prolongation and a history of syncope, cardiac arrest, or seizures or a family history of unexplained sudden death. The diagnosis should be strongly considered in any child presenting with syncope or sudden death in whom polymorphic VT or multiform ventricular premature beats are documented. Incidental QT prolongation in an asymptomatic child (with a negative family history) may warrant further scrutiny. Finally, all infants presenting with second-degree or third-degree AV block should be evaluated for the possibility of long QT syndrome (Fig. 35.15).[4]

FIG. 35.15 Congenital long QT syndrome presenting with 2 : 1 atrioventricular block. The corrected QT interval is greater than 560 ms, resulting in "functional" block of every other sinus beat in the His-Purkinje system.

Patients with symptoms or arrhythmias associated with QT prolongation require careful evaluation for secondary causes, which include CNS injury, hypocalcemia, hypokalemia, and drugs that prolong the QT interval. The list of drugs that prolong the QT interval is extensive and includes antiarrhythmic and noncardiac drugs, most of which block I_{Kr}, the rapid component of the delayed rectifier potassium current.[47] Updated lists of these drugs are available at www.crediblemeds.org.

Torsade de pointes is the specific arrhythmia associated with long QT syndromes and is responsible for the symptoms (Fig. 35.16). This characteristic arrhythmia is recognized by progressive undulation in the QRS axis, resulting in a "twisting" appearance, and is usually associated with a specific initiation with a VPB following a pause (often following a previous VPB). Many episodes are not sustained, and even prolonged episodes may terminate spontaneously. Torsades de pointes that degenerates to ventricular fibrillation requires defibrillation.

FIG. 35.16 Torsades des pointes in a teenage patient with long QT syndrome. This arrhythmia is associated with no pulse and results in syncope. It often terminates spontaneously but otherwise rapidly degenerates to ventricular fibrillation.

Because the stress caused by defibrillation may trigger recurrent arrhythmias, defibrillation should be performed in an unconscious or sedated patient. Treatment of immediate recurrence of torsades de pointes is challenging and includes magnesium sulfate, increasing the heart rate with temporary pacing or isoproterenol, and sedation.[48] For most acquired long QT syndromes (and some congenital forms), increasing the heart rate using isoproterenol or by pacing shortens the QT interval, but isoproterenol may exacerbate some forms of the congenital long QT syndrome.[49] Therefore isoproterenol should be used only when there is underlying bradycardia and cardiac pacing cannot be started immediately. Correcting hypokalemia, hypomagnesemia, or hypocalcemia and removing potentially causative agents may be important in the ICU setting.

Ventricular Tachycardia in Ostensibly Healthy Patients

Accelerated ventricular rhythm is observed occasionally in neonates in the first few days of life at rates only slightly faster than the appropriate sinus rates. The rhythm competes with the sinus mechanism, and alternation between sinus and ventricular rhythm with fusion beats is common. The rhythm is self-limited, does not usually result in hemodynamic compromise, and carries a good prognosis. No specific therapy is necessary unless rates are excessive.[50] A similar rhythm is seen in older children and usually has a similarly benign course.[51] Two other characteristic VTs may be seen in otherwise healthy children and adolescents. One arises from the right ventricular outflow tract, resulting in a left bundle branch block pattern with inferior QRS axis. This pattern may be incessant, in which case the term *repetitive monomorphic VT* has been used. The other arises from the posterior fascicle of the left-sided conduction system, producing a right bundle branch block pattern with leftward QRS axis (Fig. 35.17). This tachycardia has been called fascicular, or verapamil-sensitive VT. Interestingly, the response to verapamil may result in misclassification as “SVT with aberrant conduction.”

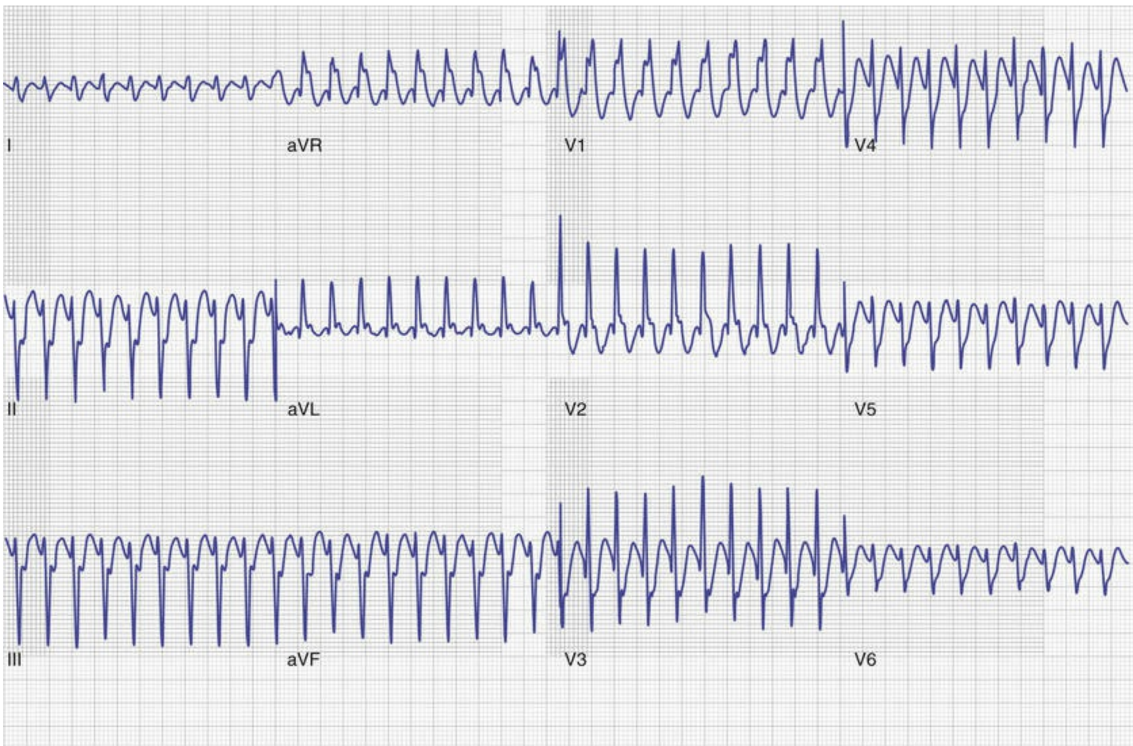

FIG. 35.17 Idiopathic ventricular tachycardia in an otherwise healthy 12-year-old. Note right bundle branch block pattern with superior axis, typical of origin within the left posterior fascicle region of the left ventricular septum.

Although VT can be seen without any apparent underlying heart disease, a rigorous search for occult heart disease is often fruitful. Cardiac tumors (rhabdomyomas, fibromas, hamartomas) and myocarditis can be associated with ventricular arrhythmias.[52]

Secondary Rhythm Disturbances

Certain arrhythmias characteristically follow operative treatment of congenital heart disease (CHD). Among those observed in the early postoperative period are complete heart block, JET, and primary atrial tachycardias. Late postoperative arrhythmias include ventricular arrhythmias following tetralogy of Fallot repair and atrial arrhythmias following the Mustard/Senning and Fontan procedures.

Postoperative Arrhythmias

Postsurgical Atrioventricular Block

Inadvertent damage to the AV conduction system may occur with cardiac surgery, especially after closure of ventricular septal defects (particularly associated with l-loop ventricles), during resection of septal tissue, or after insertion of prosthetic valves in the tricuspid, aortic, or mitral position. Bradycardia from AV block can be initially managed using isoproterenol to accelerate the ventricular rate or with epicardial temporary pacing wires placed at surgery. Although temporary pacing frequently is necessary for rate support, permanent pacemaker implantation should usually be delayed 7 to 14 days to allow for potential recovery of AV conduction. Most patients who recover AV conduction do so within 9 days of surgery.[53]

Junctional Ectopic Tachycardia

JET immediately following cardiac surgery may be mistaken for third-degree AV block, but on rewarming ventricular rates approach or exceed 200 bpm. Atrial wires or esophageal electrography confirms the key diagnostic features: AV dissociation with normal QRS and the regular ventricular rate faster than the atrial rate. Appropriately timed atrial systoles conducted to the ventricle result in “advancement” of the tachycardia cycle (without a change in QRS morphology or subsequent pause). If the QRS is normal but the RR interval does not shorten with appropriately timed atrial systoles, JET with retrograde (VA) conduction or third-degree AV block with JET as the escape rhythm should be suspected.

Infants with JET usually are often severely ill, and β-adrenergic agonists, fever, and endogenous catecholamines accelerate the tachycardia. Initial treatment of postoperative JET includes sedation and analgesia, withdrawal of adrenergic stimulants (to the extent possible), and cooling. The tachycardia may be suppressed by temporary overdrive (atrial) pacing, by pacing at a rate sufficient to produce 2 : 1 AV block, or by AVT mode pacing to provide AV synchrony.[54] IV amiodarone has been used with perhaps the greatest efficacy.[55] Although emergency radiofrequency ablation has been performed in rare instances, aggressive temporizing measures, including extracorporeal membrane oxygenation, appear warranted given the transient nature of this arrhythmia.

Late Postoperative Arrhythmias

Atrial tachycardia and bradycardia are common late sequelae following the Senning and Mustard operations for D-transposition of the great arteries, atrial septal defect closure, and the Fontan procedure for tricuspid atresia and single ventricle.[15] Patients with these arrhythmias appear to be at increased risk for sudden death, although whether death is the result of atrial tachycardia itself, associated

bradycardia, degeneration to VT, or even nondysrhythmic events remains unclear.

Likewise, in patients with repaired or palliated CHD, ventricular arrhythmias that are associated with risk for sudden death may develop. There seems to be little justification for empirical drug therapy to suppress asymptomatic ventricular arrhythmias in these patients. Earlier repair is believed to decrease the incidence of serious problems. Still, the relative contributions of postoperative hemodynamic abnormalities, the natural history of the unrepaired lesions, and surgical technique to the development of late arrhythmias remain uncertain. Similarly, the roles of pacemaker/defibrillator therapy, prospective electrophysiologic study, and antiarrhythmic drug testing are not well established. Because both bradycardias and tachycardias develop in many patients, the correlation of symptoms with electrophysiologic abnormality is important in guiding therapy.

Metabolic Derangements

Electrolyte Disturbances

Hyperkalemia causes characteristically tall ("peaked" or "tente") T waves with a narrow base with progressive changes at higher concentrations, including decreased P-wave amplitude, QRS prolongation, SA nodal and AV nodal block, and ultimately ventricular fibrillation. Mild to moderate hypokalemia may cause prominent U waves, diminished T-wave amplitude, T-wave inversion, and fusion of the T wave and U wave, along with increased spontaneous ventricular ectopy and inducible ventricular arrhythmias. Arrhythmias caused by hypokalemia are potentiated by catecholamines, and hypokalemia itself potentiates the toxic effects of digoxin and the proarrhythmic effects of drugs associated with drug-induced long QT syndrome.[56] Severe hypokalemia is associated with ventricular fibrillation.

Hypercalcemia produces T-wave inversion and shortens the QT interval. Hypocalcemia prolongs the time to the peak of the T wave but not the QT interval itself. Isolated calcium abnormalities are uncommon, and arrhythmias caused by such abnormalities are rare, although hypercalcemia may aggravate digitalis toxicity.[2]

Endocrine Disorders (Thyroid)

Hyperthyroidism exerts both sympathetic-like and direct cardiovascular actions that produce sinus tachycardia and atrial fibrillation, but ventricular arrhythmias are uncommon. These arrhythmias respond to β-blockers and resolve when the euthyroid state is restored. Combination treatment with digoxin potentiates AV nodal block while minimizing negative inotropic effects. Hypothyroidism causes sinus bradycardia and AV conduction disturbances; QT interval prolongation is common but rarely associated with torsades de pointes.[57]

Central Nervous System Injury

The most common ECG change associated with CNS trauma and increased intracranial pressure is sinus bradycardia, usually with associated hypertension. These bradycardias appear to be vagally mediated and usually respond to atropine. However, potentially serious arrhythmias may occur within 24 hours following blunt trauma to the head, subdural hematoma, and subarachnoid hemorrhage. QT-

interval prolongation is common and, in combination with bradycardia and hypokalemia, may provoke torsades de pointes.

Hypothermia and Hyperthermia

Mild hypothermia can cause a range of reversible ECG changes, including sinus bradycardia; prolongation of the PR, QRS, and QT intervals; and a characteristic secondary deflection on the terminal portion of the QRS (Osborn wave).[58] Severe hypothermia may cause more significant bradycardias, including AV block and asystole or VTs and ventricular fibrillation. Therapeutic hypothermia is associated with QT prolongation, and torsades de pointes has been reported.[59] In contrast, hyperthermia causes sinus tachycardia and may enhance other tachycardias such as PSVT, ectopic atrial arrhythmias, and especially JET in susceptible patients.

Acute Myocardial Infarction

Acute myocardial infarction is uncommon in young patients but may occur in cases of anomalous origin of the left coronary artery, when there is perinatal stress, following Kawasaki disease, with blunt chest wall trauma, and following cardiac transplantation and the arterial switch procedure. It can occur after air embolism in cyanotic CHD or after open-heart operations. The diagnosis may be overlooked in infants and children because of the inconsistency of symptoms and relatively poor (60%) clinical recognition by electrocardiography.[60] Nevertheless, acute infarction may result in various rhythm disturbances, including sinus bradycardia (as a result of the Bezold-Jarisch reflex), AV conduction disturbances, intraventricular block, and asystole.

Arrhythmias Resulting From Drug Toxicity

Digoxin

Digoxin toxicity may cause various arrhythmias and should be suspected in any patient in whom a new arrhythmia develops during digoxin therapy. Likewise, digoxin ingestion should be considered in patients with acute arrhythmias, particularly those associated with CNS and gastrointestinal symptoms. Accelerated junctional rhythm may be the first arrhythmia seen. Progressive AV block is common. Sinus bradycardia resulting from either SA node exit block or sinus arrest may occur, as can atrial fibrillation (but usually not atrial flutter). Ectopic atrial arrhythmias may occur. Nearly any ventricular arrhythmia may occur, including multiform ventricular extrasystoles, bigeminy, VT (particularly "bidirectional" VT, otherwise only seen in rare genetic arrhythmia syndromes; Fig. 35.18), and ventricular fibrillation.[61]

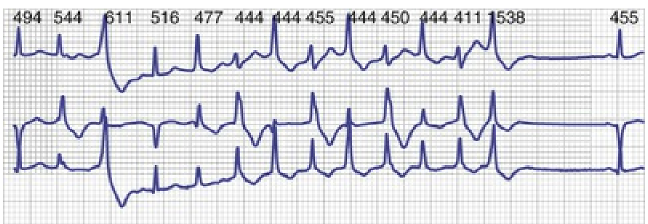

FIG. 35.18 Bidirectional ventricular tachycardia. This unusual arrhythmia is only seen in patients with digoxin toxicity and two rare genetic arrhythmia syndromes: Andersen-Tawil syndrome (periodic paralysis and ventricular arrhythmias) and catecholaminergic polymorphic ventricular tachycardia. The patient is asymptomatic during this arrhythmia, but patients appear to be at risk for ventricular fibrillation.

In general, digoxin concentrations less than 2 ng/mL are considered nontoxic. Neonates usually tolerate levels as high as 3.5 ng/mL. Nevertheless, neonates and other intensive care patients may be more susceptible to digoxin toxicity because of renal dysfunction, electrolyte imbalances, and hypoxia. Hypokalemia, excessive calcium infusions, and rapid sinus rates exacerbate digitalis-related arrhythmias.

Purified digoxin-specific Fab antibody fragment, which binds the drug and is eliminated in the urine, is used to treat digoxin toxicity. Prophylactic treatment with this preparation should be gauged according to the quantity ingested, the time since ingestion, and the serum digoxin level. Magnesium sulfate is a useful temporizing treatment while specific antibody treatment is being implemented. Cardioversion should be reserved for life-threatening tachycardias or those unresponsive to these therapies.

Cocaine

Life-threatening ventricular arrhythmias, cardiac arrest, and myocardial infarction can occur in healthy individuals with normal coronary arteries following cocaine ingestion and in prenatally exposed neonates.[62,63] Cocaine produces myocardial ischemia and infarction by inducing severe local coronary vasoconstriction, increasing myocardial-metabolic demand through its potent chronotropic effects, and increasing afterload. In infarct models, cocaine directly potentiates arrhythmias induced by catecholamines.[64] These factors favor the use of β-adrenergic antagonists as first-line treatment for cocaine-related arrhythmias. Additionally, cocaine blocks fast inward sodium channels, similar to class I antiarrhythmic agents.[65] QT prolongation and torsades de pointes have been observed.

Tricyclic Antidepressants and Phenothiazine

Phenothiazines and tricyclic antidepressants produce electrophysiologic (and potentially antiarrhythmic) effects similar to quinidine and procainamide. They slow conduction velocity in atrial and ventricular tissue, prolong repolarization, and exert anticholinergic effects accounting for the observed ECG changes of conduction disturbances, prolonged QT intervals and QRS duration, and various tachycardias and bradycardias.[66] Sinus tachycardia, atrial and VTs, and AV conduction disturbances distal to the AV node occur occasionally during normal therapeutic administration and may reflect individual susceptibility to QT-prolonging agents.

Arrhythmias commonly follow intentional overdose, resulting in hypotension (due to α-blocking effects), severe anticholinergic effects (neuromuscular and mucosal), seizures, and coma. Quinidine and procainamide are contraindicated for tachycardias because of these agents. In patients manifesting early cardiotoxicity, arrhythmias may develop 3 to 7 days following ingestion, apparently because of release of tissue stores. Therefore ECG monitoring should be continued for at least 24 to 48 hours after apparent ECG and rhythm normalization and longer if severe arrhythmias are observed.

Infections

Myocarditis may cause atrial and VTs or acquired heart block. Lyme disease may produce high-grade acute AV block. Although AV conduction usually normalizes with appropriate antibiotic therapy, temporary pacing may be required.[67] Antibiotic treatment should be instituted on the basis of the history and electrocardiographic findings alone while awaiting confirmatory serology. Bacterial endocarditis can cause AV conduction disturbances, particularly when the aortic valve is involved. Unstable or persisting conduction abnormalities (longer than 7 days) carry a high risk of mortality (43%–80%) and are indications for early valve replacement.[68]

Myocarditis may be responsible for some cases of VT in otherwise healthy individuals and may range from chronic ventricular ectopy or tachycardia to fulminant and refractory arrhythmias leading to electromechanical dissociation. Chaotic atrial tachycardia may occur in the setting of infection with respiratory syncytial virus, although the cause of this association is unclear. Finally, paroxysmal tachycardias of any etiology may be exacerbated by acute infections that cause fever, dehydration, and increased sympathetic tone. Short-term modifications of chronic therapy may be necessary, particularly when oral administration becomes impractical.

CHAPTER 36

Shock States

Lincoln S. Smith, Srinivasarao Badugu, Lynn J. Hernan

PEARLS

- Shock is recognized by the features of tachycardia, tachypnea, and abnormalities of perfusion, as evidenced by skin perfusion, quality of pulses, mental status, and dysfunction of other organ systems.
- Pediatric patients with shock often present with myocardial dysfunction ("cold" shock), although older children and adolescents may present with the adult picture of vascular dysfunction ("warm" shock).
- Neonates in shock must be treated for both septic shock and cardiogenic shock resulting from ductal-dependent congenital heart disease until an echocardiogram can confirm the cardiac anatomy. These conditions cannot be ruled out by physical examination. Therefore all neonates with shock should be given prostaglandin infusion as part of their resuscitation. Pulmonary hypertension, hypocalcemia, and hypoglycemia frequently complicate shock in neonates.
- Pediatric patients in shock generally have absolute or relative hypovolemia, and the first line of resuscitation should be a fluid bolus of 20 mL/kg. Administration of more fluid should be based on rapid assessment of hemodynamic status.
- Early endotracheal intubation allows advantageous redistribution of the compromised cardiac output and reduces left ventricular afterload.
- Timely recognition and early aggressive goal-directed therapy reduce mortality in septic shock.

The clinical syndrome of shock is one of the most dramatic, dynamic, and life-threatening problems faced by the physician in the critical care setting. Although untreated shock is universally lethal, mortality may be considerably reduced with rapid, proper recognition; diagnosis; monitoring; and treatment.

Definition and Physiology

Shock is an acute, complex state of circulatory dysfunction that results in failure to deliver or use sufficient amounts of oxygen and other nutrients to meet tissue

metabolic demands. If prolonged, it leads to multiple organ failure and death. Therefore shock can be viewed as a state of acute cellular energy deficiency. Shock can be caused by any serious disease or injury, but whatever the causative factors, it is always a problem of inadequate cellular sustenance. It is the final common pathway to death.

Delivery of oxygen (DO_2) is a direct function of cardiac output (CO) and arterial oxygen content (CaO_2):

Delivery of oxygen:

$$DO_2 = CO \times CaO_2 \qquad \textbf{Eq. 36.1}$$

Cardiac output:

$$CO = \text{Heart rate (HR)} \times \text{Stroke volume (SV)} \qquad \textbf{Eq. 36.2}$$

Oxygen content:

$$CaO_2 = (Hgb \times 1.34 \times SaO_2) + (0.003 \times PaO_2) \qquad \textbf{Eq. 36.3}$$

Stroke volume is a function of preload, afterload, contractility, and diastolic relaxation. Therefore optimizing heart rate, contractility, diastolic relaxation, preload, and afterload improves cardiac output. Oxygen-carrying capacity can be increased by raising hemoglobin and optimizing its saturation with oxygen. Oxygen delivery can be improved by manipulation of all these factors.

Calculation of global oxygen delivery may not reflect regional hypoperfusion and localized ischemia. Inadequate oxygen delivery can result from either limitation or maldistribution of blood flow. Reduced oxygen content (anemia, low arterial oxygen saturation) necessitates higher cardiac output to maintain oxygen delivery. In certain situations (fever, sepsis, trauma), metabolic demands may exceed normal oxygen delivery. Impairment of the extraction or utilization of oxygen by cells and mitochondria creates a functional arteriovenous shunt and may be the harbinger of multiorgan dysfunction syndrome.[1,2]

Recognition and Assessment of the Shock State

The early diagnosis of shock requires a high index of suspicion and knowledge of conditions that predispose children to shock. Interviews of the parents, physicians, nurses, and emergency medical services personnel caring for the child provide valuable information. A rapid and focused physical examination of a patient in shock is essential (Box 36.1).

Box 36.1

Physical Assessment in Shock

State of consciousness: restless, anxious, agitated, comatose
Skin: temperature, perfusion, moistness, color, turgor, rash
Mucous membranes: color, moistness
Nail beds: color, capillary refill
Central capillary refill
Peripheral veins: collapsed or distended
Pulse: rate, rhythm, quality
Blood pressure: orthostatic changes, pulse pressure
Respiration: rate, depth, effort, crackles, adequacy of aeration
Urine: concentration, hourly output

Shock states have been divided into three phases: compensated, uncompensated, and irreversible (Box 36.2). In compensated shock, vital organ function is maintained primarily by intrinsic regulatory mechanisms. The ability to compensate for shock states varies with age and depends on developmental aspects of the autonomic nervous, circulatory, respiratory, renal, and immunologic systems, as well as the presence of other medical conditions. Previously healthy children can compensate for and maintain normal blood pressure during states of reduced delivery and/or increased oxygen demand. Diagnosing a patient as having compensated shock, rather than mere dehydration, may be the difference between a patient who is appropriately resuscitated in a timely manner and one for whom resuscitative efforts are delayed.

Box 36.2

Shock States

Hypovolemia
Cardiogenic
Obstructive
Distributive
Septic
Endocrine

Early signs of compensated shock may be subtle. Activation of peripheral and central baroreceptors produces catecholamines, and the resulting tachycardia and peripheral vasoconstriction are initially adequate to support blood pressure. Tachypnea, mildly prolonged capillary refill, orthostatic hypotension, and mild alteration of mental status (eg, lethargy, irritability) are signs of compensated shock. In patients with sepsis, other signs of early compensated shock may be plethora, warm extremities, bounding pulses, and a widened pulse pressure.

As shock progresses, compensatory mechanisms are exceeded, and oxygen delivery is no longer sufficient. Patients become hypotensive, acidotic, lethargic or comatose, and oliguric or anuric. Cellular function deteriorates, affecting all organ systems. Systemic vasoconstriction and hypotension produce ischemia and hypoxia in the visceral and cutaneous circulations. Altered cellular metabolism and function result in damage to blood vessels, kidneys, liver, pancreas, and bowel.

Terminal or irreversible shock implies damage to key organs of such magnitude

that death occurs even if therapy restores cardiovascular function to adequate levels.

The contribution of laboratory tests to the initial evaluation of patients in shock is limited. Blood gases and serum lactate levels may quantify the degree of hypoxemia and acidosis and are widely used as markers for the effectiveness of treatment. Serum lactate[3-7] and troponin I[8,9] may be useful markers of severity of illness and for prognosis. Systemic mixed venous oxygen saturation greater than 70% suggests adequate cardiac output, but this assumes normal oxygen extraction.[10] However, an increased understanding of microcirculatory aberrations and cellular hypoxia has raised awareness of the limitations of tests on pooled venous samples. This has stimulated a search for a minimally invasive means of sampling regional circulations.[11-13] Gastric tonometry,[14,15] near-infrared spectroscopy,[16,17] rectal tonometry,[18] sublingual capnometry,[19,20] muscle oxygenation,[21] tissue microdialysis,[22,23] and orthogonal polarization spectral imaging[24,25] are investigational methods to evaluate regional circulation, but their clinical utility remains unproven at this time. Repeated evaluations and monitoring of the patient in shock by a competent observer, with appropriate, timely interventions, remain the most effective and sensitive physiologic monitor available.

Treatment of Shock

General Principles

In addition to treatment of the primary underlying process, therapeutic efforts involve optimizing and balancing oxygen delivery and oxygen consumption. Therapy begins with the assurance of adequate oxygenation and ventilation; oxygen should always be the first drug administered. Efforts to reduce oxygen requirements when oxygen delivery is compromised are important. Sedation, paralysis, and control of fever are ways to reduce oxygen consumption. Even routine nursing procedures can increase oxygen consumption by up to 20% to 30% in healthy adults.[26]

Intubation and Mechanical Ventilation

During shock states, there is often increased work of breathing related to capillary leak, acidosis, and hypoxemia. In landmark studies in dogs, spontaneous breathing during shock states was associated with preserved blood flow and oxygen consumption by the diaphragm and intubation, paralysis, and mechanical ventilation resulted in redistribution of cardiac output from the muscles of respiration to vital organs.[27,28] A subsequent study in humans showed that central venous hypoxemia significantly improved after intubation and mechanical ventilation.[29] Although these data suggest that mechanical ventilation can substantially improve oxygen delivery to vital organs, suboptimal patient-ventilator interactions may result in increased oxygen consumption.[30,31] Positive pressure ventilation decreases preload and increases afterload on the right ventricle (see Chapter 34). The reduction of preload can often be overcome by treating the patient with a rapid fluid bolus before or during intubation. Positive pressure ventilation also reduces afterload to the left ventricle, which may improve stroke volume.

Fluid Resuscitation

Regardless of the underlying insult, most patients in shock have an absolute or relative hypovolemia, causing a decrease in preload and subsequent decrement of stroke volume and cardiac output. Early fluid resuscitation is the cornerstone of immediate therapy. Landmark studies of septic pediatric and adult patients showed that early fluid resuscitation was associated with improved patient outcomes, and these principles are incorporated in current treatment guidelines.[32-34] However, excessive fluid resuscitation in patients with cardiogenic shock and some forms of obstructive shock (massive pulmonary embolism or severe pulmonary hypertension) may rapidly push the patient over the Frank-Starling curve into congestive heart failure. Multimodal monitoring uses multiple variables and their changes over time to assess hemodynamic status and prognosis: Heart rate variability,[35] shock index[36] (HR/SBP), and speckle tracking imaging[37] have shown promise. Evidence associating positive fluid balance with increased mortality in critically ill adult and pediatric patients[38-41] suggests a need for better predictors of fluid responsiveness and end points of fluid resuscitation.[42,43] Therefore careful attention must be paid to the physiologic responses to fluid resuscitation by a competent observer. When sufficient preload has been achieved through fluid resuscitation but the patient remains in shock, other supportive therapies are indicated.

Inotropic, Chronotropic, Lusitropic, and Vasoactive Infusions

Infusions to increase cardiac output and improve peripheral vascular tone are indicated when patients have been adequately fluid resuscitated but hemodynamics remain deranged. Infusions of catecholamines (dopamine, dobutamine, epinephrine, norepinephrine); phosphodiesterase inhibitors (milrinone); and vasopressin are most commonly used. The choice of vasoactive infusion is dependent on the physiologic derangement (Table 36.1). Catecholamines work through stimulation of α_1, α_2, β_1, β_2, and dopaminergic receptors to increase intracellular cyclic guanosine monophosphate (cGMP) (Table 36.2). Phosphodiesterase inhibitors increase cGMP by preventing its degradation within the cell (see Chapter 33). Vasopressin causes vasoconstriction by direct stimulation of vascular smooth muscle cell V1 receptors. Vasopressin also potentiates systemic adrenergic effects. Vasopressin and terlipressin (a synthetic analog of vasopressin with a similar pharmacodynamic profile but with a significantly longer half-life) have also shown some utility in the treatment of catecholamine-resistant shock.[44-46] Fenoldopam has been used to augment diuresis and improve hemodynamics after cardiac surgery and in septic shock.[47,48] There is not conclusive generalized evidence that the choice of medication influences outcome in critically ill adults.[49] Therefore therapies should be tailored to the unique patient situation, and patients should be closely monitored for expected responses.[35]

TABLE 36.1

Therapies for Hemodynamic Patterns in Shock States

	BLOOD PRESSURE OR SYSTEMIC VASCULAR

Hemodynamic Pattern	RESISTANCE		
	Normal	Decreased	Elevated
Septic shock			
Stroke index ↑ ↔	None	α_1, V_1	None
Stroke index ↓	β_1	α_1 and β_1	$\beta_1 + \beta_2$, or PDE
Cardiogenic shock	β_1	α_1 and β_1	$\beta_1 + \beta_2$, or PDE
Myocardial dysfunction (complicating critical illness)[a]	β_1 and/or β_2	α_1 and β_1	$\beta_1 + \beta_2$, or PDE
Congestive heart failure	β_1 and/or β_2	β_1	$\beta_1 + \beta_2$, or PDE
Bradycardia	None	β_1	None

[a]For example, acute respiratory distress syndrome or anthracycline therapy.

PDE, phosphodiesterase inhibitor.

TABLE 36.2

Vasoactive Medications

	α_1	β_1	β_2	D_1	V_1
Dopamine[a]	Vasoconstriction	Inotropy, chronotropy	Vasodilation	Renal vasodilation	
Norepinephrine	Vasoconstriction	Inotropy			
Epinephrine[b]	Vasoconstriction	Inotropy, chronotropy	Vasodilation		
Dobutamine		Inotropy	Vasodilation		
Vasopressin	Potentiates	Potentiates			Vasoconstriction
Inamrinone, milrinone		Non–receptor-mediated inotropy, lusitropy, and vasodilation			

[a]Dose related: at low infusion rates, D_1 receptor effects predominate; at intermediate rates, β_1 and β_2 receptor effects predominate; at high rates, α_1 effects predominate on peripheral vasculature.

[b]Dose related: at low infusion rates, β receptor effects predominate; at high rates, α effects predominate on peripheral vasculature.

Other Therapies

The finding of hypocalcemia in infants who present in shock should raise the suspicion of left ventricular dysfunction. Hypocalcemia causes left ventricular dysfunction and is reversible with calcium therapy. Of note, 30% of neonates with DiGeorge syndrome are hypocalcemic.

Neonates, who have low glycogen stores and increased metabolic requirements during shock, may quickly develop hypoglycemia. Patients with mitochondrial disorders may also be highly sensitive to reductions in energy substrates. All patients in shock should be monitored and treated with appropriate energy substrates.

Adrenal insufficiency should be suspected in patients with refractory shock resulting from trauma (head or abdominal), history of steroid use within past 6 months, sepsis, or treatment with etomidate. Direct damage to the hypothalamus, anterior pituitary, or adrenals may result in cortisol deficiency. In septic shock, adrenal hemorrhage has been the paradigm of adrenal insufficiency, but evidence of transient relative or functional adrenal insufficiency in septic shock remains unclear (see section on septic shock).

Extracorporeal life support (ECLS) has been used to support patients of all ages with shock. The Extracorporeal Life Support Organization (ELSO) maintains a database of patients treated with ECLS from member institutions around the world. The registry was searched for data on patients treated with ECLS (from 1985 through

January 2010) with any mention of the diagnosis of shock. The registry revealed 1512 pediatric patients (age ≤21 years old) who were treated with ECLS for any diagnosis that included the descriptor shock. The overall mortality was 60%. Sixty-five percent of patients were 1 year of age or younger, and 44% were neonates. In patients aged 21 years or younger treated with ECLS, the etiology of shock was cardiogenic (46%), septic (22%), hypovolemic (11%), traumatic or surgical (1%), and other or unspecified (20%). The mortality across the groups ranged from 56% to 64%.

Multisystem Effects of Shock

Management of the multisystem deterioration that occurs in shock states is as important as treating the underlying condition. Respiratory, gastrointestinal, central nervous system, renal, and hematologic abnormalities must be anticipated. Multiple organ dysfunction syndrome (MODS) is the derangement of two or more organs after an insult.[50] The severity of MODS has been associated with increased mortality in PICU patients.[51-54]

Respiratory

Respiratory failure frequently accompanies shock states. It may result from failure of the ventilator pump (ie, respiratory muscle fatigue) and/or deterioration of lung function (ie, acute respiratory distress syndrome). Therefore providing supplemental oxygen is essential in all children with shock. Early tracheal intubation protects the airway, provides relief from respiratory muscle fatigue, facilitates provision of positive airway pressure, redistributes blood flow from the muscles of respiration to core organs, reduces the left ventricle afterload, and reduces oxygen demands of respiratory muscles. Patients should be ventilated with a lung protective strategy (see Chapter 52).

Renal

Renal failure may develop in association with any of the shock syndromes. Shock-related renal failure is a continuum of acute prerenal azotemia through classic acute tubular necrosis to cortical necrosis. Although low-dose dopamine (3–5 μg/kg/min) improves renal blood flow,[55,56] it also impairs renal oxygen kinetics, inhibits protective feedback loops with the kidney, may worsen tubular injury, and has failed to show benefit in preventing or altering the course of acute renal failure in adults.[57,58] Acute anuric renal failure may require treatment with peritoneal dialysis, ultrafiltration, continuous hemofiltration or hemodiafiltration, or hemodialysis (see Chapter 78). Populations for whom early renal replacement therapies result in decreased mortality have not been consistently identified, but there is evidence that fluid overload is associated with mortality in critically ill children with renal dysfunction.[59] If renal dysfunction exists, all medications and therapies should be adjusted for creatinine clearance. High-output renal failure may occur in shock states without previous oliguria. The polyuria associated with this condition may falsely suggest adequate renal perfusion and adequate vascular volume at a time when the patient's intravascular volume is, in fact, depleted. Restoration of renal perfusion pressure remains the standard of care.

Coagulation

Coagulation abnormalities (eg, disseminated intravascular coagulation) probably occur to some extent in all forms of shock. Monitoring of prothrombin time, partial thromboplastin time, and platelet count and observation for abnormal bleeding are essential. Replacement therapies of absent clotting factors seem to be the most advantageous treatments. Use of vitamin K, fresh-frozen plasma, cryoprecipitate, and platelet transfusions should correct most coagulopathies. If general replacement therapy is ineffective and the patient is at risk for complications, specific factor therapy may be indicated (see "Septic Shock" later).

Hepatic

The degree of hepatic dysfunction may determine a patient's ultimate outcome in severe shock states. Maintaining adequate circulation helps maintain liver function and prevents further hepatocellular damage. Liver function tests should be performed early and followed frequently. If dysfunction exists, drugs requiring hepatic metabolism must be carefully titrated.

Gastrointestinal

Acute nonocclusive mesenteric ischemia is a devastating condition characterized by intense, prolonged splanchnic vasoconstriction; intestinal mucosal hypoxia; and acidosis. Mesenteric ischemia eventually leads to transmural necrosis of the bowel, bacterial translocation, sepsis, and multisystem organ dysfunction.[60-62] Morbidity and mortality for this condition are high because the signs and symptoms are nonspecific. Prevention of gut ischemia through adequate oxygen delivery may prevent bacterial translocation. Some clinicians advocate the use of selective gut decontamination and early enteral nutrition.[63,64] Most children with shock will tolerate postpyloric enteral feeding, although gastrointestinal feeding complications are more common than in critically ill patients without shock.[65,66] Other gastrointestinal disturbances after hypoperfusion and stress include bleeding, ileus, and bacterial translocation. Ileus may result from electrolyte abnormalities, administration of narcotic medications, or shock itself. Abdominal distension from ileus or ascites may cause respiratory compromise, especially in infants. The substantial morbidity and mortality of upper gastrointestinal bleeding due to "stress-related mucosal damage" have led to widespread prophylactic use of medications to suppress gastric acid production, but the benefit of this practice remains unproven.[67,68]

Endocrine

Multiple endocrine problems involving fluid, electrolytes, and mineral balance may arise and complicate the management of children in shock. Severe abnormalities of calcium homeostasis can occur during the course of acute hemodynamic deterioration. Patients who have been administered corticosteroids within 6 months preceding the onset of shock should be considered for stress doses of glucocorticoids. Patients in shock because of head or abdominal trauma may have disruption of the hypothalamic-anterior pituitary-adrenal axis. Adrenal hemorrhage

has been demonstrated as a manifestation of severe sepsis, but more commonly patients may develop a relative or functional adrenal insufficiency. Dopamine may also inhibit secretion of prolactin, growth hormone, and thyrotropin in critically ill children.[40]

Functional Classification and Common Underlying Etiologies

Shock states can be classified into six functional categories (Box 36.2). Such tidy classification implies a degree of precision that will be misleading when approaching an individual patient. Vicious cycles play a prominent role in most shock syndromes. Any given patient, over time, may display features of any functional category or features of multiple categories. Hemodynamic profiles of these categories are summarized in Table 36.1.

Hypovolemic Shock

Hypovolemia is the most common cause of shock in infants and children. Etiologies include hemorrhage, fluid and electrolyte loss, endocrine disease, and plasma loss (Box 36.3). Acute losses of 10% to 15% of the circulatory blood volume may be well tolerated in healthy children who have intact compensatory mechanisms. An acute loss of 25% or more of the circulating blood volume, however, frequently results in hypovolemic shock that requires immediate, aggressive management.

Box 36.3

Etiologies of Hypovolemic Shock

I. Whole blood loss

A. Absolute loss: hemorrhage

1. External bleeding

2. Internal bleeding

a. Gastrointestinal

b. Intraabdominal (spleen, liver)

c. Major vessel injury

d. Intracranial (in infants)

e. Fractures

B. Relative loss

1. Pharmacologic (barbiturates, vasodilators)

2. Positive pressure ventilation

3. Spinal cord injury

4. Sepsis

5. Anaphylaxis

II. Plasma loss

A. Burns

B. Capillary leak syndromes

1. Inflammation, sepsis

2. Anaphylaxis

C. Protein-losing syndromes

III. Fluid and electrolyte loss

A. Vomiting and diarrhea

B. Excessive diuretic use

C. Endocrine

1. Adrenal insufficiency

2. Diabetes insipidus

3. Diabetes mellitus

Once the airway is assured or established, measures to restore an effective circulating blood volume should begin immediately. Placement of an adequate intravenous or intraosseous catheter and rapid volume replacement are the most important therapeutic maneuvers to reestablish the circulation. The choice of fluid depends on the nature of the loss. Hemorrhagic shock should be treated with

transfusions of blood components, including emergency transfusion of uncrossmatched blood.[69,70] The hematocrit may be a poor early indicator of the severity of hemorrhage. Concomitant with colloid resuscitation of hemorrhagic shock, early surgical intervention may be indicated to control the source of bleeding.[71]

Isotonic crystalloid solutions, which are readily available, safe, and the least expensive, should be used in initial volume resuscitation for all other patients with hypovolemic shock. The first fluid bolus (20 mL/kg) should be administered as rapidly as possible. The amount of fluid necessary to restore effective circulating blood volume depends on the amount lost (deficit) and the rate of ongoing loss. The total amount of fluid given often exceeds the total volume lost because of expanded capacitance of the vascular space and dysfunction of cellular membranes. Ongoing fluid losses from chest tubes, biliary drains, bowel, capillary leak, or other losses of bodily fluids may dictate the use of solutions other than crystalloid.

The end point of fluid resuscitation should be normalization of arterial blood pressure, pulse pressure, peripheral perfusion, and heart rate. Uncomplicated, promptly treated hypovolemic shock usually does not lead to a significant capillary injury and leak. However, severe, prolonged hypovolemic shock, traumatic shock with extensive soft tissue injury, burn shock, or sepsis complicating hypovolemic shock may seriously impair capillary integrity. Therefore once adequate hemodynamics have been restored, fluid administration may be reduced unless there are demonstrable ongoing fluid losses. Continued assessment of hemodynamic status and vascular volume is essential to guide further therapy.

If the patient does not show improvement after several isotonic fluid boluses, more aggressive monitoring and reevaluation of the diagnosis may be required. Causes of ongoing vascular depletion should be sought, as well as other causes of refractory shock including unrecognized pneumothorax or pericardial effusion, intestinal ischemia (volvulus, intussusception, necrotizing enterocolitis), sepsis, myocardial dysfunction, adrenocortical insufficiency, and pulmonary hypertension. Arterial blood gases, hematocrit, serum electrolytes, glucose, and calcium should be reevaluated. Correction of acidosis, hypoxemia, or metabolic derangements is essential. Blood and other appropriate sites must be cultured and broad-spectrum parenteral antibiotic coverage begun if sepsis is suspected.

Cardiogenic Shock or Congestive Heart Failure

Cardiogenic shock or congestive heart failure (CHF) during infancy and childhood is a diagnostic and therapeutic challenge because of its myriad etiologies (Box 36.4). The common denominator in all forms of cardiogenic shock is depressed cardiac output. In most instances the underlying mechanism is systolic dysfunction or "pump failure." Cardiogenic shock can also be caused by diastolic dysfunction, as seen in postoperative patients, ischemic heart disease (anomalous left coronary artery from pulmonary artery [ALCAPA]), or disorders associated with ventricular hypertrophy.[72,73] Lack of myocardial relaxation increases left ventricular end-diastolic pressure resulting in pulmonary edema. Elevated left ventricular end-diastolic pressure also decreases myocardial perfusion pressure and can lead to subendocardial ischemia. Abnormalities of the heart rate and rhythm can also cause cardiogenic shock. While bradyarrhythmias cause low cardiac output due to

decreased heart rate, atrioventricular dyssynchrony and tachyarrhythmias cause low cardiac output due to inadequate diastolic filling. Tachyarrhythmias also increase the myocardial oxygen consumption and compromise myocardial perfusion. Finally, myocardial dysfunction is frequently a late manifestation of shock of any etiology. It is important to understand the underlying pathophysiology of cardiogenic shock as therapy designed to improve certain conditions may also adversely affect prognosis in other conditions.[73]

Box 36.4

Etiologies of Cardiogenic Shock

I. Heart rate abnormalities

A. Supraventricular tachycardia

B. Ventricular dysrhythmias

C. Bradycardia

II. Congenital heart defects

A. Lesions with ductal dependent systemic blood flow in neonates (CoA, Critical AS, IAA, HLHS)

B. Left-to-right shunt lesions

C. Single ventricle dysfunction

D. Systemic ventricular dysfunction (L-TGA)

E. Ischemic cardiomyopathies (ALCAPA)

III. Cardiomyopathy, carditis

A. Hypoxic-ischemic events

1. Cardiac events

2. Prolonged shock

3. Head injury

4. Anomalous coronary artery

5. Excessive catecholamine state

6. Cardiopulmonary bypass

B. Infectious

1. Viral

2. Bacterial

3. Fungal

4. Protozoal

5. Rickettsial

6. Sepsis

C. Metabolic

1. Systemic lupus erythematosus

2. Juvenile rheumatoid arthritis

3. Polyarteritis nodosa

4. Kawasaki disease

5. Acute rheumatic fever

E. Neuromuscular disorders

1. Duchenne muscular dystrophy

2. Myotonic dystrophy

3. Limb girdle (Erb)

4. Spinal muscular dystrophy

5. Friedreich ataxia

6. Multiple lentiginosis

F. Toxic reactions

1. Sulfonamides

2. Penicillins

3. Anthracyclines

G. Other

1. Idiopathic dilated cardiomyopathy

2. Familial dilated cardiomyopathy

ALCAPA, anomalous origin of the left coronary artery from the pulmonary artery; *AS*, aortic stenosis; *CoA*, coarctation of the aorta; *Erb*, limb girdle musculodystrophy or scapulohumeral limb-girdle muscular dystrophy; *HLHS*, hypoplastic left heart syndrome; *IAA*, interrupted aortic arch; *L-TGA*, levo-transposition of great arteries.

Evaluation

The appropriate management of heart failure is dependent upon the specific etiology; accurate and rapid diagnosis is of prime importance. Recognition begins with a careful history and physical examination (Box 36.5) and is supplemented by noninvasive tests such as chest radiography, electrocardiography, and echocardiography. Further diagnostic workup may include laboratory investigations, cardiac catheterization, and endomyocardial biopsy.

Box 36.5

Recognition of Congestive Heart Failure in Infants

History	Excessive respiratory effort Prolonged feeding time Poor weight gain Excessive sweating Frequent respiratory tract infections
Physical examination	Tachycardia Tachypnea Gallop rhythm Cold extremities Weak peripheral pulses Wheezing, rales Dyspnea, cough Cyanosis Diaphoresis Hepatomegaly Neck vein distension Peripheral edema Hypotension
Chest radiograph	Cardiomegaly Pulmonary venous congestion Hyperinflation

Electrocardiography may give diagnostic hints by demonstrating chamber enlargement, ischemic changes, and arrhythmias. Two-dimensional and Doppler echocardiography has become the cornerstone for evaluation and management of children with cardiogenic shock. It is useful in diagnosing structural abnormalities and gives valuable information about the left ventricular volume, stroke volume, wall thickness, and contractility. Doppler investigation of the diastolic mitral inflow pattern is useful in assessing diastolic dysfunction.[73]

Nonspecific markers of inflammation (white blood cell count, C-reactive protein, and erythrocyte sedimentation rate) are often elevated in congestive heart failure caused by myocarditis. B-type natriuretic peptide and N-terminal pro-B-type natriuretic peptide can be elevated in myocarditis, and elevated levels may aid in distinguishing a cardiac from a noncardiac reason for respiratory symptoms in children. Confirmation of myocardial inflammation by endomyocardial biopsy may be required for a definitive diagnosis of myocarditis.[74]

Therapy

Box 36.6 lists the general supportive and pharmacologic measures used in the treatment of severe CHF or cardiogenic shock. The initial therapy for cardiogenic shock is to support the heart with supplemental oxygen and mechanical ventilation.

Preload should be optimized to allow the patient to take advantage of Starling mechanisms. Correction of metabolic derangements (eg, pH, glucose, calcium, magnesium) may enhance cardiac function, and pharmacologic interventions are usually necessary to improve cardiac function (see Tables 36.1 and 36.2). In addition to inotropic effects, catecholamines also possess chronotropic properties and have complex effects on vascular beds of the various organs of the body. Consequently, the choice of an agent may depend as much on the state of the circulation as it does on the myocardium.

Box 36.6

General Principles in Management of Cardiogenic Shock or Severe Congestive Heart Failure

I. Minimize myocardial oxygenation demands

1. Intubation and mechanical ventilation
2. Maintain normal core temperature
3. Provide sedation
4. Improve oxygen-carrying capacity by correcting anemia

II. Maximize myocardial performance

1. Correct dysrhythmias
2. Prostaglandins if suspecting ductal-dependent lesions
3. Optimize preload: fluid boluses; if congested, appropriate salt and water restriction and appropriate use of venodilators and/or diuretics
4. Improve contractility: provide oxygen, mechanical ventilation, correct acidosis and other metabolic abnormalities, inotropic and lusitropic drugs
5. Reduce afterload: provide sedation and pain relief, correct hypothermia, positive pressure ventilation for LV afterload reduction, appropriate use of vasodilators

III. Mechanical circulatory support

1. ECMO

2. Ventricular assist devices

IV. Heart transplantation

ALCAPA, anomalous origin of the left coronary artery from the pulmonary artery; *AS,* aortic stenosis; *CoA,* coarctation of the aorta; *Erb,* limb girdle musculodystrophy or scapulohumeral limb-girdle muscular dystrophy; *HLHS,* hypoplastic left heart syndrome; *IAA,* interrupted aortic arch; *L-TGA,* levo-transposition of great arteries.

In neonates presenting in shock within the first 4 weeks of life, a lesion with ductal-dependent systemic output should be suspected and prostaglandin E_1 (PGE_1) (0.05–0.1 μg/kg/min) should be infused emergently until an echocardiogram can be obtained. This is a lifesaving intervention; opening and maintaining ductal patency is the only medical intervention that can restore adequate systemic cardiac output.

Proper use of the various vasoactive drugs often requires the presence of indwelling arterial and central venous catheters. A pulmonary artery catheter may be helpful if the patient is not responding to therapy and shock is not resolving as expected but is rarely used these days due to the potential complications. Many devices are available to measure cardiac output and other hemodynamic variables. Use of these monitoring devices allows the generation of data that will characterize the hemodynamic state, direct appropriate therapy, and allow for evaluation of the response to therapy.[75]

The digitalis glycosides may augment myocardial contractility, but because of a narrow therapeutic-to-toxic ratio, long half-life, and dependence of clearance on renal (digoxin) or hepatic function, their use in patients with cardiogenic shock should be avoided. These compounds have the advantage of improving contractility without further increasing the heart rate. They can be used once the shock is resolved.

Inamrinone, milrinone, and enoximone[76] belong to a class of nonglycoside, nonsympathomimetic inotropic agents that act via potent and selective inhibition of phosphodiesterase. Inamrinone and milrinone are particularly useful in the treatment of cardiogenic shock because they improve diastolic function (lusitropy), increase contractility, and reduce afterload by peripheral vasodilation without a consistent increase in heart rate or myocardial oxygen consumption. Both of these drugs have relatively long half-lives, and they should be used cautiously in the presence of hypovolemia and/or hypotension. Milrinone is preferred over inamrinone because of inamrinone's tendency to cause thrombocytopenia. The use of milrinone has been shown to be effective in decreasing the risk of low cardiac output syndrome in postoperative cardiac patients.[77]

Use of vasodilators in shock generally is limited to situations in which cardiac dysfunction is associated with elevated ventricular filling pressures, elevated systemic vascular resistance, and normal or near-normal systemic arterial blood pressure. Occasionally, the combination of vasodilator and inotropic therapy results in hemodynamic improvement not attainable with either approach alone. Vasodilators improve cardiac performance and lessen clinical symptoms via arterial

and venous smooth muscle relaxation. Arterial relaxation should increase ejection fraction, increase stroke volume, and decrease end-systolic left ventricular volume. Some evidence suggests some vasodilator drugs increase left ventricular compliance, which should improve diastolic function.[73] Venous relaxation should shift blood into the periphery and reduce right and left ventricular diastolic volume, with attendant beneficial effects on pulmonary and systemic capillary pressure. This ought to be reflected in decreased edema, reduced myocardial wall stress, and improved diastolic perfusion of the myocardium.

For treatment of cardiogenic shock, intravenous vasodilators with rapid onsets of action and short half-lives are preferred. Selection of a vasodilator agent should depend on its principal hemodynamic effects and the specific hemodynamic abnormalities in individual patients. Factors that increase systemic resistance, such as hypothermia, acidosis, hypoxia, pain, and anxiety, should be treated before vasodilator drugs are considered.

Afterload reduction of the failing right ventricle plays a pivotal role in some of the most frequently encountered and important cardiopulmonary disorders in children, including congenital heart disease, acute respiratory distress syndrome, bronchopulmonary dysplasia, and other chronic pulmonary disorders. The ability of the right ventricle to respond to the increased pulmonary vascular resistance seen in these situations often determines outcome. Therefore measures to decrease pulmonary vascular resistance have become more common in the treatment of many seriously ill pediatric patients. Such measures include supplemental oxygen, hyperventilation, metabolic and respiratory alkalosis, inhaled nitric oxide, prostaglandin E_1, prostacyclin, analgesia, and sedation.[78-80]

After the initial stabilization of children with cardiogenic shock, long-term management needs to be planned. Neurohumoral compensatory mechanisms that initially compensate for a fall in output of the failing heart, in time, become a major part of the problem.[75] Use of vasodilators to oppose systemic vasoconstriction and angiotensin-converting enzyme inhibitors to block the renin-angiotensin system may be necessary to break the self-perpetuating cycle caused by these neurohumoral compensatory mechanisms. Angiotensin-converting enzyme inhibitors improve ventricular function and clinical outcome in adults. However, their usefulness is not yet established in certain forms of pediatric heart failure, especially the failing single ventricle.[81]

Surgical Intervention

A number of congenital cardiac defects may present in severe CHF and cardiogenic shock. Diagnosis of these defects is critical because surgery is the definitive therapy. Prostaglandin E_1 infusion may allow for resuscitation and stabilization until surgery can be accomplished in ductal-dependent obstruction to systemic blood flow (eg, hypoplastic left heart syndrome, interrupted aortic arch, coarctation of the aorta).

Cardiac function may be supported temporarily by mechanical means, including left ventricular assist device (VAD), and ECLS. Cardiac transplantation has become an important tool for treating patients with severe myocardial dysfunction who otherwise would die of their heart disease.

Specific Etiologies

Cardiomyopathy

Patients with dilated cardiomyopathy may present in shock. The etiologies of acute dilated cardiomyopathies are listed in Box 36.7. Myocarditis is one of the more common causes of dilated cardiomyopathy in previously healthy children. Tachycardia (in the absence of fever) and tachypnea are usual presenting symptoms. In acute myocarditis, the history of illness is short (hours to days). Life-threatening dysrhythmias in patients with acute myocarditis include ventricular tachycardia and supraventricular tachycardia. Initial resuscitation of the patient with myocarditis is the same as for other forms of cardiogenic shock; however, patients with myocarditis and other dilated cardiomyopathies may not require much fluid resuscitation or respond as well to traditional inotropic therapy.[82,83] In addition, catecholamine infusions may promote the development of dysrhythmias.

Box 36.7

Organ Dysfunction Criteria

Cardiovascular	After isotonic fluid bolus ≥40 mL/kg in 1 h: Hypotension: BP <5th percentile for age *or* systolic BP <2 SD below normal age *or* Need for vasoactive drug to keep BP in normal range *or* ≥2 of the following: 1. Unexplained metabolic acidosis: base deficit >5.0 mEq/L 2. Lactic acidosis more than twice the upper limit of normal 3. Oliguria: urine output <0.5 mL/kg/h 4. Prolonged capillary refill: >5 s 5. Core to peripheral temperature gap >3°C
Respiratory	PaO_2/FiO_2 <300 in absence of cyanotic congenital heart disease or preexisting lung disease *or* $PaCO_2$ >65 torr or 20 torr over baseline *or* FiO_2 = 0.50 to keep saturations ≥92% *or* Need for invasive or noninvasive mechanical ventilation
Neurologic	GCS score ≤11 *or* Acute mental status change: decrease in GCS ≥3 points from abnormal baseline
Hematologic	Platelet count <80,000/mm³ or 50% decline in platelet count (for hematology/oncology patients) *or* INR >2
Renal	Serum creatinine ≥twice the upper limit of normal for age or twofold increase in baseline creatinine
Hepatic	Total bilirubin ≥4 mg/dL (outside neonatal period) *or* ALT twice upper limit of normal

ALT, alanine transaminase; *BP*, blood pressure; *GCS*, Glasgow Coma Scale; *INR*, international normalized ratio; *SD*, standard deviation.

Acute myocarditis in children with progressive heart failure may need mechanical circulatory support. Use of ECLS has been lifesaving in patients with acute myocarditis whose shock does not reverse with conventional therapy or in whom arrhythmias are unremitting. A number of studies have reported discharge rates of approximately 80% with approximately 60% of the patients experiencing myocardial recovery.[74] VADs have been used as a bridge to heart transplant. The primary VAD used for support in children is the pulsatile Berlin Heart EXCOR, which comes in various sizes, allowing support for infants as small as 3.5 kg. In the Berlin EXCOR trial, the mortality in patients on the device was 8%, and 87.5% of patients placed on the device received transplantations.[84]

On the basis of multiple case reports and case series, intravenous immunoglobulin (IVIG) has become part of routine practice for treating adults and children with acute myocarditis at many centers.[74] A recent meta-analysis showed that only children

beyond the neonatal period who have viral encephalitis with myocarditis may benefit from IVIG.[85] Until more data are available, IVIG for presumed viral myocarditis should not be provided as routine practice in any situation.[74]

Hypoxic-Ischemic Injury

Shock following a generalized hypoxic-ischemic episode (eg, drowning, sudden infant death syndrome) is encountered frequently in infants and children with no preexisting cardiovascular or pulmonary disease. Data have shown that shock following hypoxic-ischemic events is cardiogenic and is characterized by a low cardiac index, elevated right and left heart filling pressures, elevated systemic and pulmonary vascular resistances, decreased oxygen consumption, and elevated oxygen extraction index.[86] However, in many patients, the mean systemic arterial blood pressure is elevated, suggesting an increase in systemic vascular resistance. Studies have documented progressive systolic and diastolic myocardial dysfunction immediately after successful cardiac resuscitation.[87] All of these observations have important therapeutic implications because the increased vascular resistance and decreased cardiac output may combine to prevent adequate tissue perfusion following anoxic injury.

Perioperative management of the transplanted heart poses a unique set of challenges in addition to the regular hypoxic-ischemic injury. The determinants of cardiac output, namely heart rate and stroke volume, are significantly affected in these situations. Due to the autonomic system denervation, heart rate is mainly dependent on circulating catecholamines. Stroke volume is affected by the diastolic dysfunction caused by the "down time." Appropriate management of the donor heart, followed by immunosuppression and judicious use of inotropic, chronotropic, and lusitropic agents in the transplanted patient have improved outcomes. The most recent data from the International Society for Heart & Lung Transplantation, including patients from 1982 through June 2011, demonstrate a median survival of 19.7 years for infants, 16.8 years for children ages 1 to 5 years, 14.5 years for children ages 6 to 10 years, and 12.4 years for children 11 to 17 years of age at the time of transplantation.[88]

Cardiac Injury in Trauma

Blunt cardiac injury can cause myocardial contusion, myocardial concussion, aneurysm, septal defects, chamber rupture, valvular rupture, and bleeding into or damage to the pericardium. Each of these entities has separate presentations, although the lesions often are concurrent. Every pediatric trauma patient deserves a careful cardiac evaluation. Of note, both left and right ventricular function may be impaired significantly in children with isolated head injury. The myocardial injury seen in children with head injury appears to be related to high levels of catecholamines with resultant myocardial ischemia.[89]

Obstructive Shock

Obstructive shock is caused by the inability to produce adequate cardiac output despite normal intravascular volume and myocardial function. Causative factors may be located within the pulmonary or systemic circulation or associated with the

heart itself. Examples of obstructive shock include acute pericardial tamponade, tension pneumothorax, pulmonary or systemic hypertension, and congenital or acquired outflow obstructions. Recognition of the characteristic features of these syndromes is essential because most of the causes can be treated provided the diagnosis is made early.

Cardiac tamponade is defined as hemodynamically significant cardiac compression resulting from accumulating pericardial contents that evoke and defeat compensatory mechanisms. The pericardial space may contain effusion fluid, purulent fluid, blood, or gas. Clinical manifestations of tamponade may be insidious, especially when it occurs in conditions such as malignancy, connective tissue disorders, renal failure, or pericarditis. As cardiac output becomes restricted, the overall picture resembles CHF; however, the lungs are usually clear. Findings on physical examination that suggest cardiac tamponade include pulsus paradoxus, narrowed pulse pressure, pericardial rub, and jugular venous distension. Echocardiography is of particular value in detecting the presence of pericardial effusion and can provide clues about the presence of tamponade physiology before a patient is symptomatic. The normal effects of respiration are accentuated in cardiac tamponade. Echocardiography is useful in demonstrating the exaggerated phasic variation in cardiac volumes and flows caused by tamponade. Respiratory variation in tricuspid and pulmonary flow is more dramatic than mitral and aortic flow: With inspiration, the right ventricular early diastolic filling is augmented (>25%), while left ventricular diastolic filling diminishes (>15%). The stroke volume in the pulmonary artery increases with inspiration, while the aortic stroke volume decreases (>10%). The free walls of the right atrium and/or right ventricle collapse in diastole due to compression of these relatively low-pressure chambers by the higher-pressure pericardial effusion, and this collapse is exaggerated during expiration when right heart filling is reduced.[90]

The definitive treatment of cardiac tamponade is removal of pericardial fluid or air by surgical drainage or pericardiocentesis. Removal of even a small volume of fluid can rapidly improve blood pressure and cardiac output. Surgical drainage by either thoracotomy or a subxiphoid limited surgical approach should be considered for traumatic tamponade. Pericardiocentesis is a blind procedure; introduction of the needle should be monitored by echocardiography whenever possible. The subxiphoid approach is generally preferable (see Chapter 19).

Medical management is not a substitute for drainage but may avert a catastrophe until pericardiocentesis or surgical drainage can be safely performed. The principles of medical management include blood volume expansion to maintain venoatrial gradients and inotropic agents. In addition, any anticoagulant or thrombolytic therapy should be withheld or discontinued if pericardiocentesis is anticipated. Diuretics, which reduce blood volume, and digoxin or other agents, which slow the heart rate, are contraindicated in tamponade.

Congenital Heart Diseases With Ductal Dependent Systemic Blood Flow

Infants with critical aortic stenosis, aortic arch interruption, or juxtaductal coarctation of the aorta depend on patency of the ductus arteriosus to provide adequate lower body perfusion. Many of the signs and symptoms of coarctation

with shock are indistinguishable from shock of other etiologies.[91] A high index of suspicion must be maintained for infants who present in shock in the first month of life. In severely ill infants in whom the diagnosis of coarctation, hypoplasia, or interruption of the aorta is clinically suspected, it is appropriate and often lifesaving to start a continuous prostaglandin E_1 infusion before a more complete diagnostic evaluation is performed.

Distributive Shock

Distributive shock results from maldistribution of blood flow to the tissue and can be considered to be relative hypovolemia. Abnormalities in distribution of blood flow may result in profound inadequacies in tissue oxygenation, even in the face of a normal or high cardiac output. Such maldistribution of flow generally results from widespread abnormalities in vasomotor tone. Distributive shock may be seen with anaphylaxis, spinal or epidural anesthesia, disruption of the spinal cord, or inappropriate administration of vasodilatory medication.

Treatment generally includes reversal of the underlying etiology and vigorous fluid administration. In severe cases of distributive shock that is unresponsive to fluids, vasopressor infusions may be necessary.

Septic Shock

Septic shock is often a combination of multiple problems, including infection, relative or absolute hypovolemia, maldistribution of blood flow, myocardial depression, and various metabolic, endocrine, and hematologic problems.[92] The most common presentation (80%) in children is low cardiac index with or without abnormalities of vascular tone.[93] These children have tachycardia, mental status changes, diminished peripheral pulses, mottled cold extremities, and prolonged capillary refill (>2 seconds). In many pediatric patients with septic shock, oxygen consumption is dependent on oxygen delivery.[94] This is similar to the physiologic relationship seen in pediatric patients with cardiogenic shock, suggesting that these two groups could be resuscitated with the same physiologic principles. Adults and some children (20%) present in a hyperdynamic state characterized by an elevated (or normal) cardiac output and decreased systemic vascular resistance.[93,95] These patients appear plethoric with warm extremities. They have tachycardia, bounding (or collapsing) pulses, a widened pulse pressure, high fever, mental confusion, and hyperventilation. There may be a rapid progression from high to low cardiac output state. As tissue perfusion worsens, anaerobic metabolism ensues and lactic acid accumulates. The hemodynamic profile changes over time due to evolution of the shock state and response to therapies.[93]

All patients with septic shock present with an absolute or functional hypovolemia. Increased microvascular permeability, arteriolar and venular dilation with peripheral pooling of intravascular volume, inappropriate polyuria, and poor oral intake all combine to result in reduced effective blood volume. Volume loss secondary to fever, diarrhea, vomiting, or sequestered third space fluid also contributes to hypovolemia.

Progressive deterioration in oxygen consumption and oxygen extraction portends

a poor prognosis. Before the onset of cellular hypoxia,[2,96,97] changes in glycolysis and gluconeogenesis are early metabolic manifestations of sepsis.[98] Insulin responsiveness,[99] intracellular calcium stores,[100] glucose distribution,[101] and adrenergic effects[102] have all been implicated.

Therapy

An evidence-based guideline for the management of resuscitation and support of children and neonates with septic shock was issued in 2009, and the Surviving Sepsis Campaign updated guidelines in 2013.[33,103] Evidence-based algorithms for resuscitation for children (Fig. 36.1) and neonates (Fig. 36.2) are easy to use and have been shown to improve outcomes across diverse patient populations.[103] The emphasis remains on the first hour of fluid resuscitation and use of vasoactive infusions directed to age-appropriate goals of HR, BP, perfusion pressure (MAP-CVP), and capillary refill time of 2 seconds or less. Severity of shock states has been categorized according to hemodynamic responses (Table 36.3).[103] When resuscitation is delayed or inadequate, cellular hypoxia and multiple system organ failure ensue and are the final common pathway to death.

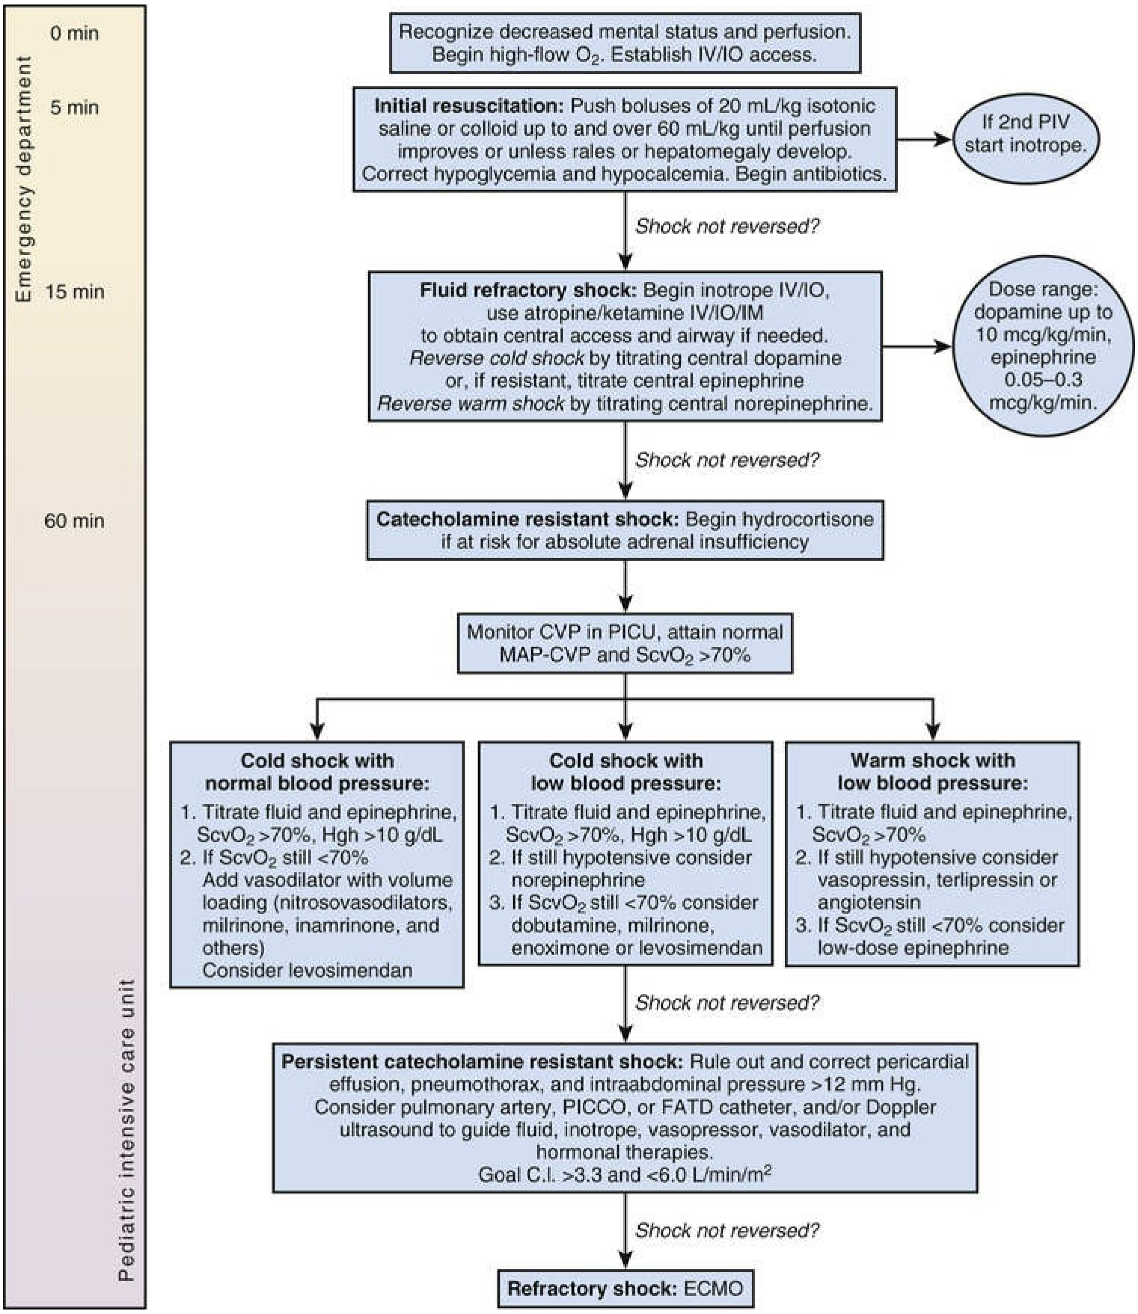

FIG. 36.1 Algorithm for time-sensitive, goal-directed stepwise management of hemodynamic support in infants and children. Proceed to next step if shock persists. (1) First-hour goals: restore and maintain heart rate thresholds, capillary refill ≤2 sec, and normal blood pressure in the first hour/emergency department. Support oxygenation and ventilation as appropriate. (2) Subsequent ICU goals: if shock is not reversed, intervene to restore and maintain normal perfusion pressure (mean arterial pressure [MAP], central venous pressure [CVP]) for age, central venous O_2 saturation >70%, and CI >3.3, <6.0 L/min/m^2 in pediatric intensive care unit (PICU). *CI,* cardiac index; *CRRT,* continuous renal replacement therapy; *ECMO,* extracorporeal membrane oxygenation; *FATD,* femoral arterial thermodilution; *Hgb,* hemoglobin; *IO,* intraosseus; *IM,* intramuscular; *IV,* intravenous; *PICCO,* pulse contour cardiac output. (Modified from Brierley J, Carcillo JA, Choong K, et al. International pediatric sepsis consensus conference: definitions for sepsis and organ dysfunction in pediatrics. Crit Care Med. 2009;37:666-688.)

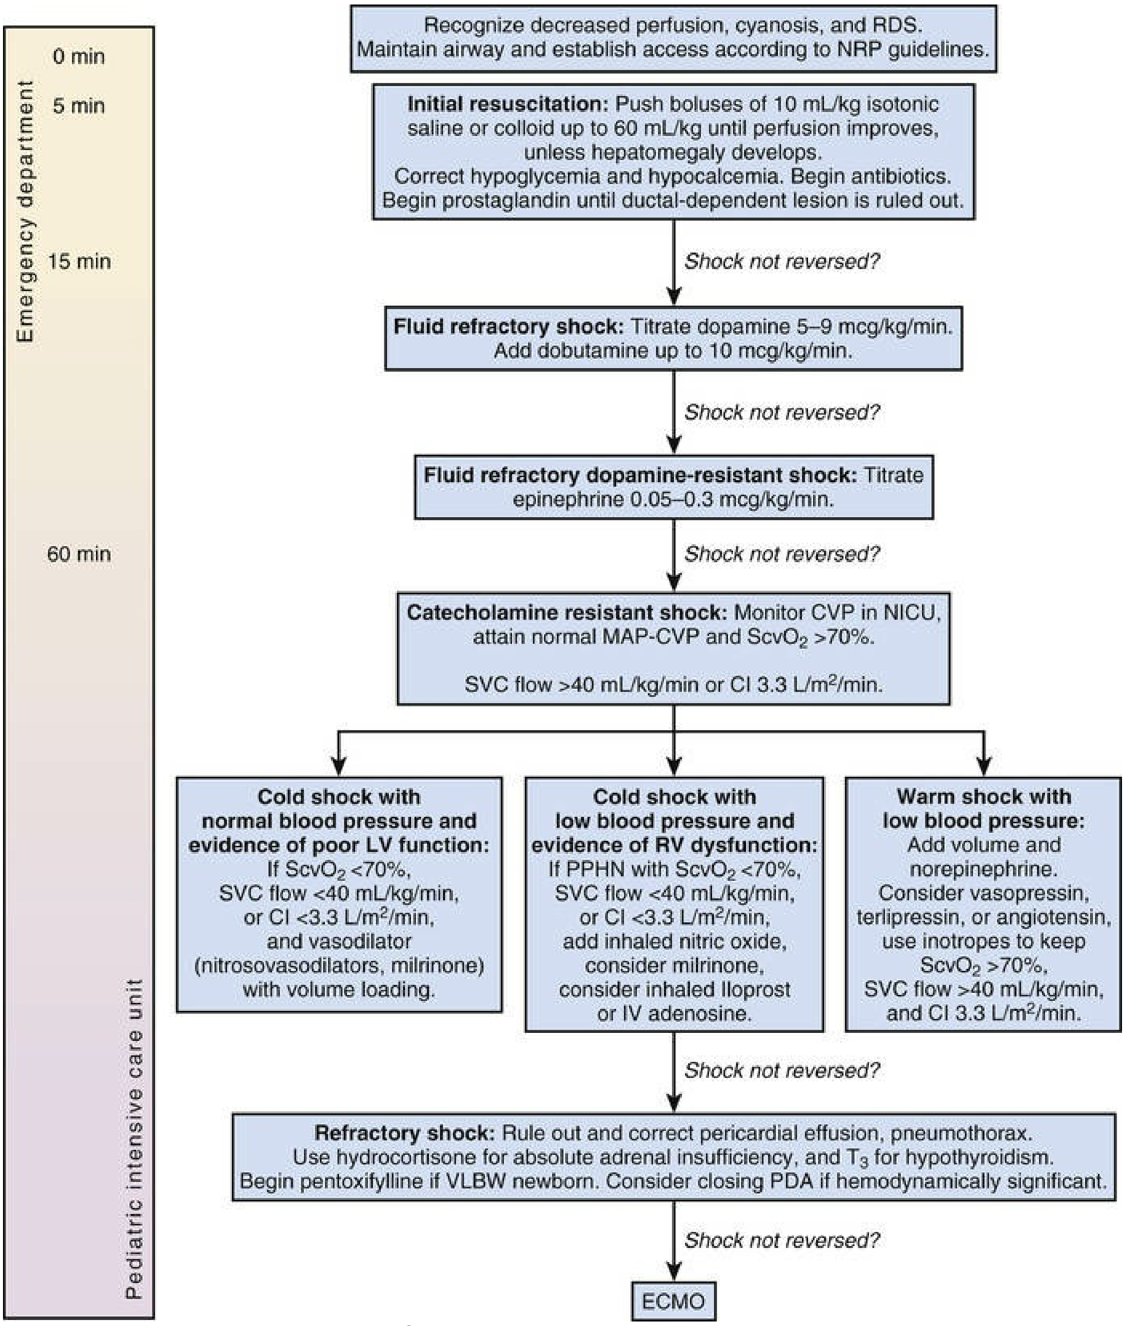

FIG. 36.2 Algorithm for time-sensitive, goal-directed stepwise management of hemodynamic support in newborns. Proceed to next step if shock persists. (1) First-hour goals: restore and maintain heart rate thresholds, capillary refill ≤2 sec, and normal blood pressure in the first hour. (2) Subsequent ICU goals: restore normal perfusion pressure (mean arterial pressure [MAP], central venous pressure [CVP]), preductal and postductal O_2 saturation difference <5%, and either central venous O_2 saturation ($ScvO_2$) >70%, superior vena cava (SVC) flow >40 mL/kg/min, or cardiac index (CI) >3.3 L/min/m^2 in the neonatal intensive care unit (NICU). *ECMO,* extracorporeal membrane oxygenation; *LV,* left ventricular; *NRP,* Neonatal Resuscitation Program; *PDA,* patent ductus arteriosus; *RDS,* respiratory distress syndrome; *RV,* right ventricular; *VLBW,* very-low-birthweight. (Modified from Brierley J, Carcillo JA, Choong K, et al. International pediatric sepsis consensus conference: definitions for sepsis and organ dysfunction in pediatrics. Crit Care Med. 2009;37:666-688.)

TABLE 36.3

ACCM Hemodynamic Definitions of Shock

Cold or warm shock	Hypoperfusion manifested by: ↓ Mental status or capillary refill >2 s (cold shock) or flash capillary refill (warm shock) *or* ↓ (cold shock) or ↑ (warm shock) peripheral pulses *or* mottled cool extremities (cold shock) or ↓ urine output <1 mL/kg/h
Fluid-refractory, dopamine-resistant shock	Persistent shock after: ≥60 mL/kg fluid resuscitation (when appropriate) and dopamine to 10 μg/kg/min
Catecholamine-resistant shock	Persistent shock after use of direct-acting catecholamines: epinephrine and norepinephrine
Refractory shock	Persistent shock despite goal-directed use of inotropes, vasopressors, vasodilators, and maintenance of metabolic (glucose, calcium) and hormonal (thyroid, hydrocortisone, insulin) homeostasis

From Brierly J, Carcillo JA, Choong K, et al. International pediatric sepsis consensus conference: definitions for sepsis and organ dysfunction in pediatrics. Crit Care Med. 2009;37:666-688.

There continues to be debate regarding the use of crystalloid or colloid solutions for volume expansion in sepsis.[104] Packed red blood cells (pRBCs) may be used if the hematocrit is less than 30% because red blood cell transfusion increases oxygen delivery to the tissues. However, expansion of oxygen-carrying capacity may not improve oxygen consumption.[105] Transfusion of pRBCs as part of a strategy to increase mixed venous oxygen saturation (SVO_2) to greater than 70% resulted in improved outcome in pediatric septic shock.[10]

Removal or control of microorganisms by surgical debridement, drainage, and antibiotic therapy is a crucial component of treatment of septic shock. Whenever possible, blood, urine, and samples from other potential infected sites should be sent for culture and susceptibility testing before broad-spectrum antibiotic therapy is initiated, but obtaining these cultures should never delay appropriate empiric antimicrobial therapy. Choice of antibiotic therapy is determined by the clinical scenario, likely organisms, and local antibiotic sensitivities.

Intubation and mechanical ventilation are also important in the resuscitation from pediatric septic shock for reasons already mentioned in this chapter. Although it has a favorable hemodynamic profile, induction with etomidate should be avoided because of its adverse effects on the adrenocortical function.[106-108]

Septic patients develop protein/caloric malnutrition as a principal manifestation of their metabolic response to sepsis.[104] In patients who were previously malnourished or remained hypermetabolic, this rapidly developing malnutrition is believed to contribute to morbidity and mortality. However, the abnormalities in intermediary metabolism make the provision of an adequate level of metabolic support challenging. Parenteral or enteral nutrition should begin as soon as cardiovascular stability is achieved. Many clinicians advocate the early use of enteral feedings to prevent gut mucosal atrophy and bacterial translocation.[65,66,109]

Experimental/Unproved Therapies

ECLS has been used to support myocardial and/or pulmonary function during sepsis. We queried the ELSO registry (1976 through January 2010) for ECMO use in all (neonatal, pediatric, and adult) patients with sepsis or septic shock. A total of 2960 patients were identified: 2409 neonates (81%) and 551 patients older than 1 month (19%). Overall survival was 67%, but there was a significant difference in the

survival of neonates versus other patients. Survival in the neonatal group was 74% versus 40% in all other patients.

Continuous renal replacement therapy (CRRT) can improve survival in critically ill (including septic) children with MODS and fluid overload.[59,110,111] Therapeutic plasma exchange has shown benefit for critically ill (some septic) children with MODS.[112-115] Exchange transfusion and plasmapheresis have potential as therapeutic interventions.[116-119] Multicenter, randomized controlled studies showing efficacy for these therapies are lacking.

The presence of adrenal insufficiency in septic shock and critical illness has been widely studied. Knowledge of the effects of inflammatory mediators on the hypothalamic-pituitary-adrenal axis has led to the concept of “functional” or “transient” adrenal insufficiency.[120-122] The effect of critical illness on adrenal function is probably more complex and involves decreased glucocorticoid receptor protein expression and decreased clearance of cortisol.[123-125]

Adult studies have shown improved hemodynamics and antiinflammatory benefits of continuous low-dose hydrocortisone infusion in adult septic shock and survival benefit associated with increased vasopressor requirement and longer duration of shock.[126-128] Steroids should be given to patients with known adrenal insufficiency or who are at risk for adrenal insufficiency (chronic or recent steroid use; purpura fulminans; etomidate or ketoconazole administration; and hypothalamic, pituitary, or adrenal disease).[103,129] The safety and efficacy of stress-dose steroids administered to pediatric patients with “transient” adrenal insufficiency are unproven and pose potential risks to patients. Pediatric studies have not shown a consistent difference in mortality rates when steroids were used.[129,130]

Many pharmacologic agents and therapies have been evaluated as adjunctive treatments in sepsis and septic shock. Recombinant activated protein C was initially promising in adults with severe sepsis. Although the subsequent series of randomized controlled trials suggest it is not beneficial for pediatric or adult septic patients, a novel meta-analysis suggests there may be benefit.[131,132] Use of plasmapheresis, plasma exchange, and plasma filtration as therapy for treating sepsis-induced multiple organ system failure and improving outcome remains experimental.[133] Other therapies with potential therapeutic usefulness include inhibitors of arachidonic acid metabolism and inhibitors of thromboxane and leukotriene formation, white blood cell transfusions, passive immunotherapy, toxic oxygen scavengers, inhibitors of myocardial depressant factors, and fibronectin administration.[95,134] Therapies targeted at modulating inflammation, such as the administration of antagonists or antibodies to various cytokines (eg, tumor necrosis factor, IL-1), showed promise in early studies but subsequently showed no benefit.[134-138] Therapies designed to modulate the immune response,[139,140] inhibit neutrophil function, or inhibit synthesis of nitric oxide (endothelial-derived relaxing factor) have demonstrated no clinical benefit in septic shock.[137] Other areas being explored with regard to the pathophysiology and treatment of septic shock include factors that inhibit apoptosis and use of insulin to maintain tight glucose control and normoglycemia.[135,139,141] These therapies have shown some promise but remain unproven.

Summary

Shock is a life-threatening condition that has a myriad of causes. In order to survive shock, recognition and resuscitative efforts must be achieved early, the etiology elucidated, and ongoing monitoring and therapy instituted. The astute clinician who recognizes shock, institutes therapy, and continuously assesses response to therapy offers the child the best chance for a quality survival.

CHAPTER 37

Pediatric Cardiopulmonary Bypass

Richard M. Ginther Jr., Joseph M. Forbess

PEARLS

- Cardiopulmonary bypass (CPB), which originated in the mid-twentieth century, was designed to allow for the repair of congenital heart defects. Its history has since been characterized by perpetual technological advancements that have been instrumental in sustaining the momentum of clinical progress of this field.
- Because of the morbidity associated with the "time on-pump," many early surgeries were performed at profoundly hypothermic temperatures by utilizing circulatory arrest.
- The current philosophy underpinning the use of pediatric CPB is to meet the metabolic demands of the patient throughout the repair while minimizing the impact of associated nonphysiologic effects.
- All aspects of CPB have experienced major technological improvements. Circuits are miniaturized and cause less blood trauma, blood component therapy is highly directed, and on-pump patient monitoring techniques have advanced.
- The progress of pediatric CPB has played a major role in the steady reduction of morbidity and mortality associated with cardiac surgery in children. Pediatric mortality rates are now comparable to those in adult patients.

Background

History

Surgery for congenital heart disease has evolved into a relatively safe intervention considering its brief history and countless hurdles. This historical journey is of course filled with triumphs and tragic failures and tells a story of progressive intuition and challenges steadily surmounted. This has culminated in the generally successful model that is used today (Table 37.1). The early years of cardiac surgery spawned many novel techniques for operations that did not rely on cardiopulmonary bypass as used today. Surgeons initiated their efforts in

cardiovascular surgery with attempts to repair extracardiac vascular anomalies such as patent ductus arteriosus and coarctation of the aorta. On August 26, 1938, at the Boston Children's Hospital, Dr. Robert Gross performed the world's first successful patent ductus arteriosus closure on a 7-year-old girl.[1] Soon, exposing the heart and attempting to correct life-threatening cardiac defects became a reality. In the early 1950s, surgeons began to explore several different approaches to repairing intracardiac defects. One technique, popularized by Dr. F. John Lewis, used total body hypothermia and vena cava inflow occlusion to achieve direct visualization of atrial septal defects.[2] Although this technique proved to be a fairly safe technique for simple atrial septal defects, failure was often the result when more complex defects were attempted.[3,4] Surgeons needed a way to safely perfuse the patient's circulatory system and extend the “safe” surgical time. In the late 1930s, Dr. John Gibbon and his wife Mary, a nurse and research assistant, began developing a heart-lung machine to do just this. By the early 1950s, Dr. Gibbon, in an interesting collaboration with International Business Machines Corporation (IBM), reported promising success in the laboratory using a heart-lung machine on cats and dogs.[5-7] After a previous fatal attempt to repair an atrial septal defect (ASD) in a 15-month-old child in February 1952, Dr. Gibbon successfully closed an ASD in an 18-year-old patient using his heart-lung machine on May 6, 1953.[8] Unfortunately, Dr. Gibbon was not able to repeat the same success with the heart-lung machine on subsequent cases, and his next four patients died. Other surgical teams devised their own versions of cardiopulmonary bypass but were unable to replicate laboratory successes, and no other human survivors were reported. It was theorized that perhaps these hearts were too sick to be repaired and that it was unrealistic to expect that these hearts could recover. Cardiopulmonary bypass became a widespread disappointment, and most investigators abandoned the technique. While others were reporting their attempts using the heart-lung machine, however,[9-12] Dr. C. Walton Lillehei and his colleagues at the University of Minnesota introduced a new approach for supporting patients during surgery: controlled cross circulation. During cross circulation, the patient's parent was used as the “heart-lung machine” and supported the patient during the operation (Fig. 37.1). Considering the potential for a 200% operative mortality, this was a highly controversial technique. However, using this method, Dr. Lillehei was able to effectively close an ASD on March 26, 1954.[13] Dr. Lillehei and his colleagues[14] continued a remarkable series of successes using cross circulation by performing 45 operations for anomalies including ventricular septal defect, atrioventricular canal, and tetralogy of Fallot, with an operative mortality of only 38%. This progress with more complex lesions prompted investigators to rethink their options for supporting, repairing, and recovering these patients. Two surgical camps ignited the resurgence of the artificial heart-lung machine: Dr. Lillehei and his colleagues at the University of Minnesota and Dr. John Kirklin and his colleagues at the nearby Mayo Clinic. Dr. Kirklin and colleagues[15] reported a 50% mortality among eight patients using a modification of the Gibbon-IBM pump oxygenator in the spring of 1955. Months later, Lillehei and colleagues[16] reported a 29% mortality among seven patients using their own heart-lung machine and the groundbreaking DeWall Bubble Oxygenator. These two groups demonstrated that surgical repair of complex congenital defects could be performed in a more controlled environment than cross circulation or inflow occlusion, with promising results. What followed were many groups initiating open-heart programs

primarily addressing congenital heart disease. Despite significant improvements in survival rates, congenital cardiac repairs remained a daunting undertaking with significant risk. Bypass circuits were enormous when compared with the patient blood volume, the systemic response was an extreme shock, and the understanding of the physiologic response to this "nonphysiologic" extracorporeal circulation was quite limited. Investigators sought to use cardiopulmonary bypass but limit the actual cumulative time that nonphysiologic blood flow is provided to the patient—with its attendant risk. The bypass circuit could be used to cool the patient down to profound hypothermia, after a lengthy period of topical cooling. The circulation of the patient could then be safely terminated for lengthy periods of time, allowing for complex cardiac repairs. At the conclusion of the repair, the heart-lung machine could be used to fully warm the patient. These hypothermic circulatory arrest techniques with limited periods of extracorporeal circulation were popularized in the early 1970s by Dr. Barratt-Boyes and proved to dramatically extend the "safe" period of support.[17] Surgeons began to perform increasingly complex congenital heart repairs. Pediatric cardiac surgical care was further refined over the subsequent several decades. The development of smaller, more efficient, and customizable heart-lung machine hardware and components, as well as improvements in myocardial protection, have allowed surgical teams to move away from the concept of limited cardiopulmonary bypass and toward a more "full-flow" philosophy wherein the metabolic demands of the body are continuously met while the patient is on the heart-lung machine. This chapter explores the concepts that form the basis of this philosophy and the techniques that surgical teams currently use to support pediatric patients during cardiovascular surgery.

TABLE 37.1

Successful Congenital Cardiac Surgery Milestones

Year	Event	Surgeon
1938	Patent ductus arteriosus ligation	Gross
1944	Coarctation repair	Crafoord
1944	Blalock-Taussig shunt	Blalock, Taussig
1946	Potts shunt	Potts
1947	Closed pulmonary valvotomy	Sellors
1948	Atrial septectomy	Blalock, Hanlon
1951	Pulmonary artery band	Muller, Dammann
1952	Atrial septal defect closure using atrial well	Gross
1952	Atrial septal defect closure using hypothermia	Lewis
1953	Atrial septal defect closure using cardiopulmonary bypass	Gibbon
1954	Ventricular septal defect closure using cross circulation	Lillehei
1958	Superior cavopulmonary shunt (Glenn shunt)	Glenn
1958	Senning operation for transposition of great arteries	Senning
1963	Mustard operation for transposition of great arteries	Mustard
1968	Fontan procedure for tricuspid atresia	Fontan
1975	Arterial switch for transposition of great arteries	Jantene
1981	Norwood procedure for hypoplastic left heart syndrome	Norwood
1985	Neonatal heart transplantation	Bailey

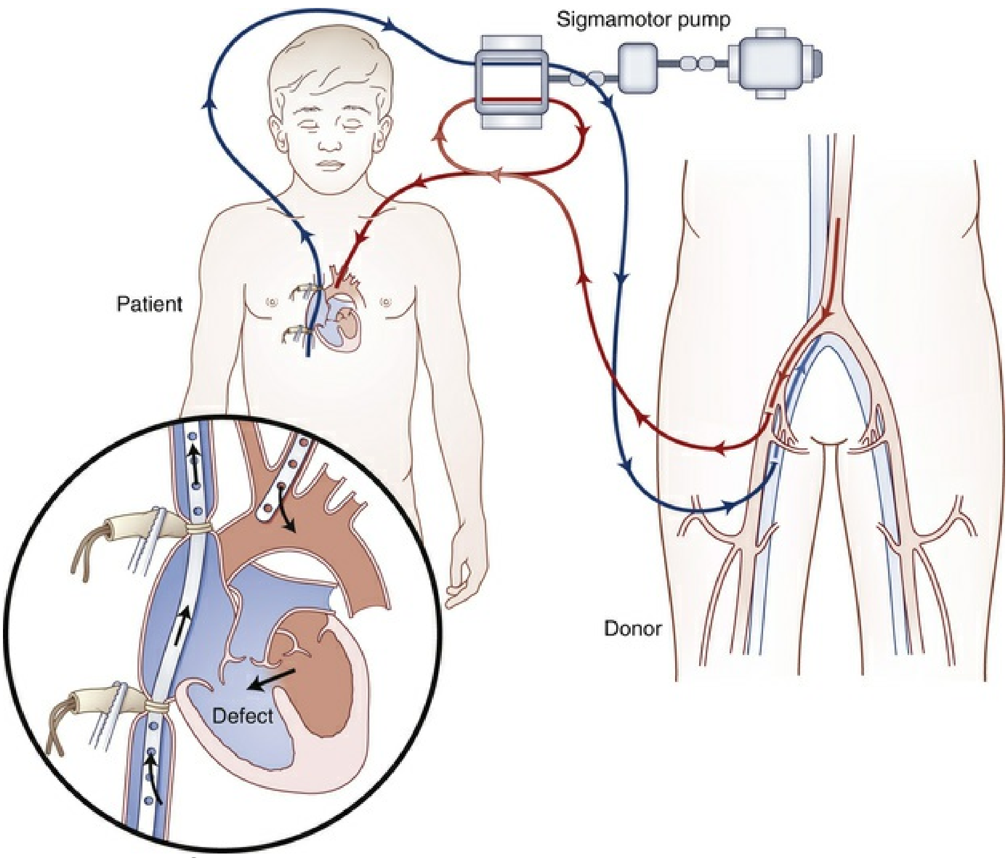

FIG. 37.1 Controlled cross circulation. (From Stoney WS. Evolution of cardiopulmonary bypass. Circulation. 2009;119:2844-2853.)

Surgical Team

The surgical team consists of highly trained specialists, each of whom plays a vital role in the safety and success of the surgical procedure. This specialized team is led by the cardiac surgeon and typically includes an assistant surgeon or physician assistant, an anesthesiologist, a perfusionist, as well as several nurses, surgical scrub technologists, anesthesia assistants, and perioperative surgical assistants.

A perfusionist is a health care professional who specializes in all aspects of extracorporeal circulation. The primary focus of a perfusionist is to support the cardiac surgical patient during cardiopulmonary bypass. Because of this, the perfusionist's clinical expertise is a critical component of operative success. Perhaps the first perfusionist was Mary Gibbon, Dr. Gibbon's wife. In addition to helping design the Gibbon-IBM heart-lung machine, she assembled and operated it as well. The term *perfusionist* did not emerge until the early 1970s, and in the early days of cardiac surgery, surgical groups would typically use any locally available combination of physiologists, biochemists, cardiologists, or surgical residents to help operate the heart-lung machine. Now, cardiovascular perfusionists are highly trained, nationally certified (CCP; Certified Clinical Perfusionist), state-licensed allied health professionals. The common scope of practice for a perfusionist consists of cardiopulmonary bypass (CPB), extracorporeal membrane oxygenation (ECMO), isolated limb/organ chemoperfusion, ventricular assist device (VAD), autotransfusion, and intra-aortic balloon counterpulsation.

Equipment and Preparation for Cardiopulmonary Bypass

Heart-Lung Machine Console and Pumps

The cardiopulmonary bypass (CPB) machine, commonly referred to as the heart-lung machine, is the mechanical hardware that a perfusionist uses to support the patient during surgery. Until the late 1950s, the CPB hardware and circuitry were typically handmade, and many of the components had to be hand washed and sterilized for reuse. The hardware components were designed at that time with two objectives: to pump blood through the patient's cardiovascular system and to successfully perform respiratory gas exchange, hence the term “heart-lung machine.” Unfortunately, this heart-lung apparatus was large, difficult to move, had no safety features, and was not available to other institutions eager to operate. Surgeons interested in these handcrafted devices would often visit the surgical groups at the University of Minnesota and Mayo Clinic, but few could replicate their expensive and intricate systems. Eventually, industry developers began to commercially release heart-lung machines with hardware components consolidated onto a wheel-mounted console. Interestingly, although cardiac surgery began with the pediatric patient population, heart-lung machines were developed as “one-size-fits-all” units and were not customizable for smaller patients.

Modern heart-lung machine consoles are mobile, offer many pump configuration options, and are loaded with safety features. These design improvements allow for better configuration options for the pediatric surgical population. An ideal heart-lung machine for pediatric CPB is customizable for circuit miniaturization and offers safety devices and hardware that accommodate both smaller tubing sizes and circuitry. Customizations such as mast mounting pumps in various configurations and incorporating mini–roller pumps with shorter raceway lengths are two popular heart-lung machine configurations.[18,19]

Several different types of mechanical pumps have been used to substitute the function of the heart, and interestingly, the roller pump has remained a standard pump mechanism since the beginning of cardiopulmonary bypass. A roller pump functions by positive fluid displacement. Tubing is placed in a curved raceway, and as occlusive rollers rotate over the compressible tubing, blood is pushed forward creating a continuous nonpulsatile flow. The flow output is controlled by changing the revolution per minute (RPM) of the pump. Roller pumps are the most commonly used arterial (heart) pump in pediatrics (Fig. 37.2).[20] While roller pumps are used as the arterial pump, the heart-lung machine console also holds several other roller pumps used for cardiotomy field suction, venting the heart, and cardioplegia delivery.

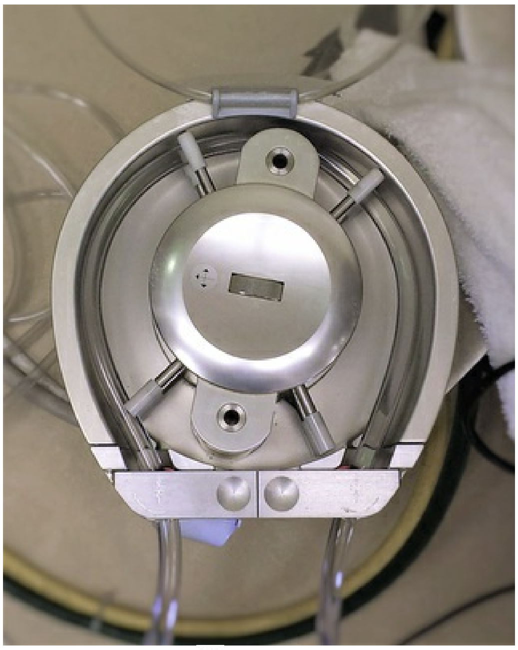

FIG. 37.2 Roller pump with $\frac{1}{4}$-inch tubing placed in the raceway.

The centrifugal pump is another type of arterial pump that has gained significant popularity since the mid-1970s. A centrifugal pump uses an impeller cone and rotational kinetic energy to propel the blood, and because it is nonocclusive, it is thought to be safer and cause less hemolysis than roller pumps. Centrifugal blood flow is controlled by the impeller cone RPMs and is also dependent on preload and sensitive to resistance distal to the pump. Because the pump is not occlusive, any resistance or occlusion will result in a reduction or cessation of flow. These pumps require the use of a flow probe to measure actual flow, and the nonocclusive property is considered a safety feature in the event of cannula obstruction or accidental arterial line occlusion. The use of centrifugal pumps during ECMO has become increasingly popular due to the suggested hemolytic and safety benefits; however, these benefits have often been refuted.[21-24] Roller pumps remain the main arterial pump type in pediatric CPB because they are simple, inexpensive, and, importantly, require a much smaller prime volume than centrifugal pumps.

Cardiopulmonary Bypass Circuit

The handmade circuits used on children in the mid-1950s were elaborate, and the large blood volume required to prime them was a burden on the blood bank. Perfusionists would have to spend the evening of surgery assembling the circuit and then tackle the tedious task of dismantling, rewashing, and sterilizing the same circuitry after surgery. Fortunately, manufacturers now offer a wide variety of disposable circuit components that are fairly simple to assemble. The modern CPB circuit is a series of components consisting of cannulas, tubing, venous reservoir, filters, oxygenator, heat exchanger, hemoconcentrator, suction, and cardioplegia delivery system.

Deoxygenated blood from the superior vena cava (SVC) and inferior vena cava (IVC) travels down a venous line, usually pulled by simple gravitational siphon effect, and into a venous reservoir. The deoxygenated blood in the reservoir is

pumped through the oxygenator and then back to the patient's aorta (or other major artery) via the arterial line (Fig. 37.3). This blood pathway diverts blood away from the heart and lungs, creating a bloodless operative field. In the adult patient population, where the circuit prime volume is typically no greater than 25% of the patient's blood volume, a single circuit size can be used for almost all patient sizes. The small circuit prime-to-patient blood volume ratio helps to minimize patient hemodilution during CPB and ultimately reduces the likelihood of donor blood exposure. The same adult circuit, with a prime volume of about 1 L, would be approximately 500% of the circulating blood volume in a neonate. This discrepancy would seem outrageous considering current circuit options, but the prime-to-blood volume ratio was even higher before manufacturers began to release pediatric oxygenators in the mid-1980s. Since the oxygenator is one of the largest volume components of the CPB circuit, any significant reduction in size would result in large prime volume reductions. A circuit miniaturization movement began, and the new clinical challenge in pediatric CPB was to reduce both circuit prime volume and surface area. The goal of circuit prime and surface area reduction is to minimize hemodilution and the deleterious effects of foreign surface blood contact activation. Strategies such as using smaller diameter and shorter tubing lengths and incorporating neonatal and pediatric CPB components have allowed clinicians to reach this goal. At Children's Health Dallas, the perfusionists have made many circuit modifications to achieve a static prime volume of approximately 165 mL in our neonatal circuit. This prime volume lowers the circuit size to approximately 45% of the blood volume of a 3-kg patient (Fig. 37.4).

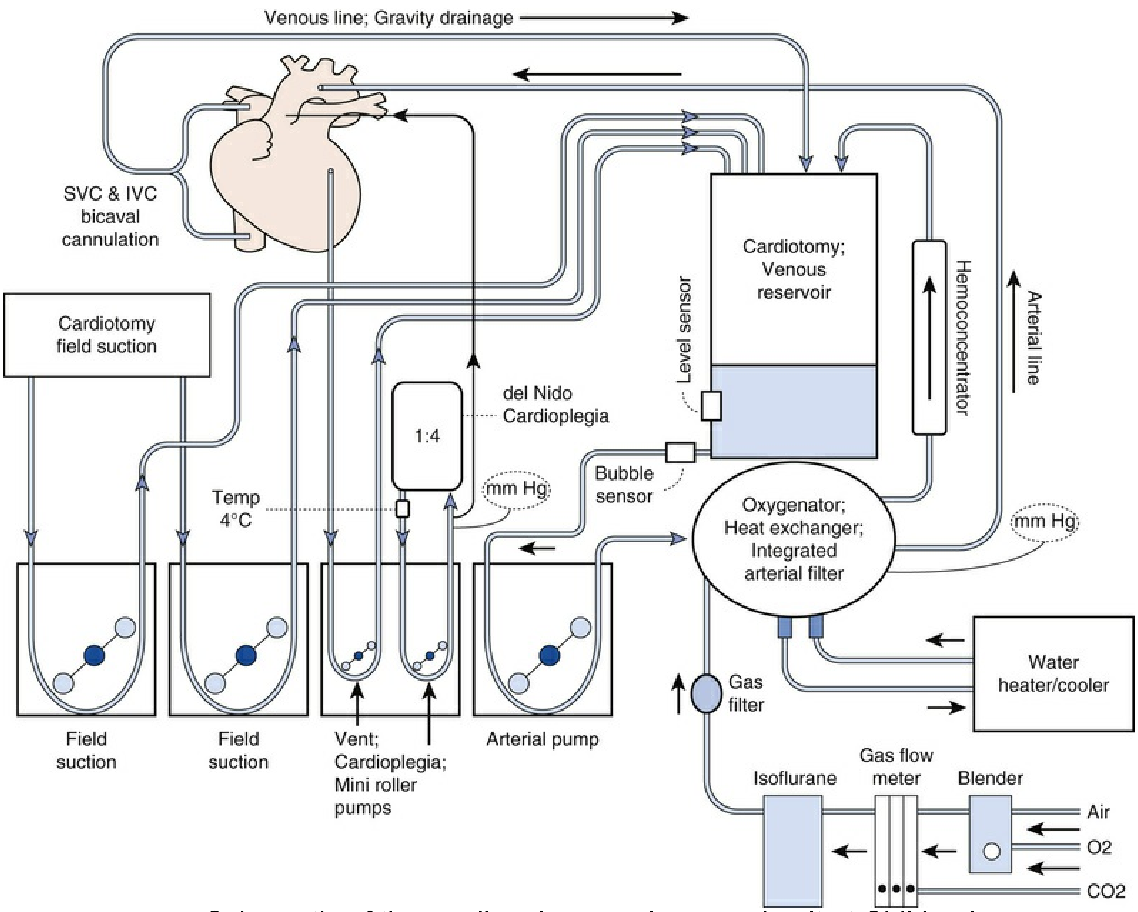

FIG. 37.3 Schematic of the cardiopulmonary bypass circuit at Children's Health Dallas.

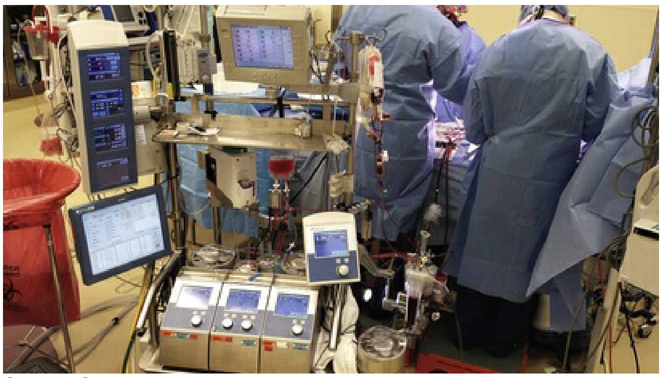

FIG. 37.4 Sorin S5 heart-lung machine with mast mounted arterial pump and Terumo Baby FX reservoir and oxygenator at Children's Health Dallas.

Oxygenators

An oxygenator, the artificial lung of the CPB circuit, might be considered the most important component of the circuit. It is responsible for oxygen and carbon dioxide (CO_2) gas exchange, as well as volatile anesthetic administration. A heat exchanger,

used for cooling and warming the perfusate, and hence the patient, is housed inside the oxygenator, and certain newer models now integrate the arterial filter, to reduce particulate matter, into the oxygenator. A venous reservoir, which includes both venous line and cardiotomy suction filters and various ports for drug and fluid administration, is typically packaged with an oxygenator. Currently, hollow fiber membrane oxygenators, which fully separate the blood flow from gas flow by a thin polymer membrane, are used during CPB. A brief history of oxygenator development reveals much about some of the important "engineering" solutions that have allowed for cardiac surgery to be performed more safely, in progressively smaller patients.

The first oxygenators used in the early days of cardiac surgery were hardware units that either used rotating discs or large mesh screens. These oxygenators worked by creating a large surface area film of blood, either over rotating discs in a pool of venous blood or trickling over large mesh screens, and exposing the film of blood to an oxygenated atmosphere.[25,26] Though these units were successful at oxygenating blood, they required extremely large priming volumes; were not disposable; were difficult to assemble, operate, and clean; and lost significant efficiency during hemodilution. In addition to these disadvantages, these oxygenators were not commercially available to clinicians looking to operate beyond the University of Minnesota and Mayo Clinic.

The University of Minnesota team dramatically changed this landscape in the late 1950s by releasing the simple, disposable, inexpensive, and commercially available DeWall-Lillehei bubble oxygenator.[27] Though the safety of actively adding bubbles to the blood was debated, the commercial availability of this device contributed to a rapid global expansion of cardiac surgery. The bubble oxygenator was a distinct improvement over the previous unwieldy direct blood contact oxygenators, yet it was still limited in that the direct blood air interface could produce significant blood trauma. This trauma accrues over time, so the safety margin for longer pump runs was diminished for longer, complex cases.

The next generation of oxygenators, membrane oxygenators, better mimicked the function of the lungs. These microporous, gas-permeable membranes eliminated direct contact between gas and blood, thus reducing blood trauma.[26] The concept of a microporous membrane separating the gas and blood was sound, but it took decades of research to find a suitable membrane material before these oxygenators could replace bubble oxygenators commercially. Initial success with silicone membranes was observed with long-term support during ECMO; however, in the operating room these membranes proved to be less efficient, prone to plasma leakage and thrombus formation.[26,28] The development and release of polypropylene microporous membranes allowed for efficient gas exchange over a wide range of temperatures and pump flow rates and soon replaced the bubble oxygenator during CPB in the mid-1980s. In these oxygenators, CO_2 and O_2 flow meters and a gas blender control gas and volatile anesthetic flow through the inside of the hollow polypropylene fibers. The gas within the hollow fibers passively diffuses into the blood flowing on the outside of the fibers.

In 1985 Cobe released the popular Variable Prime Cobe Membrane Lung (VPCML) designed for the pediatric market. This oxygenator was divided into separate compartments and gave clinicians three maximum blood flow options, 1.3, 2.6, and 4.0 L per minute (LPM), depending which compartments were opened.[29]

The VPCML also tried a new concept with the heat exchanger. Once a separate external CPB component, the stainless steel heat exchanger was placed inside the venous reservoir. The stainless steel coil wrapped around the inside of the reservoir was not efficient unless a large amount of volume was held in the reservoir. This was counter to the efforts to reduce the overall circuit prime volume. Despite this shortcoming in the VPCML model, the move toward integration and consolidation of functionalities continued. These heat exchangers are now integrated within the oxygenator housing. Considering that pediatric cardiac surgery is more likely than adult surgery to use moderate to deep hypothermia, these heat exchangers need to be extremely efficient with a small surface area.

As technology relentlessly improved, membrane hollow fibers were wrapped into tighter configurations. This eventually allowed for a priming volume low enough to release a dedicated neonatal oxygenator. In 2006, Dideco released the first neonatal oxygenator with a prime volume of 31 mL and max rated flow of 700 mL/min.[30] The new generation of neonatal and pediatric oxygenators achieves much higher maximum flow rates while keeping prime volumes appropriate for neonates. This has allowed clinical teams to achieve consistent physiologic outcomes after pump runs in neonates and small infants. A modern pediatric device like the Terumo Baby FX oxygenator with integrated arterial filter (Terumo Cardiovascular Group, Ann Arbor, Michigan, USA) offers a low total prime volume and a high maximum blood flow (Fig. 37.5). With arterial filter integration, this oxygenator has a total prime volume of 43 mL and a maximum rated blood flow of 1.5 LPM. This low prime oxygenator is suitable for neonates but also accommodates patients up to approximately 15 kg. This wide range of blood flow and low prime improves the likelihood of bloodless surgery—wherein an asanguineous prime is used—for the larger patients in range for this device. The Maquet Quadrox-i Neonatal oxygenator (Maquet Holding B.V. & Co. KG, Rastatt, Germany) is another oxygenator with an integrated arterial filter that has a 40-mL total prime volume and 1.5-LPM maximum flow. When considering the additional volume of an external arterial line filter, this high-efficiency oxygenator with an integrated filter offers the lowest total prime volume unit on the market today.[31] Current trends in oxygenator design and development include integration of the arterial line filter, biocompatible surface coatings for circuit tubing, decreasing flow resistance, and more efficient heat exchange.

FIG. 37.5 Picture of the Terumo Baby FX05 pediatric oxygenator.

Tubing

The tubing used to connect the various components of the CPB circuit to the patient is made of a medical-grade polyvinyl chloride (PVC). Tubing length and diameter are the two main factors to consider when designing a circuit. Shorter tubing with the smallest internal diameter will reduce prime volume, but the tubing must also be large enough to safely manage required blood flows and line pressures for a given patient. In the past, $\frac{1}{4}$-, $\frac{3}{8}$-, and $\frac{1}{2}$-inch tubing were the only tubing options and thus made circuit miniaturization a difficult task. Currently, a wide range and selection of pediatric tubing and connector sizes are available, and tubing sizes such as $\frac{1}{8}$, $\frac{3}{16}$, and $\frac{1}{4}$ inch have become the new standards in pediatrics. Changing the internal diameter of tubing affects blood flow resistance and must not impede venous drainage or arterial blood flow. At our institution, we select arterial-venous line sizes that accommodate gravity venous drainage and do not exceed an arterial line pressure of 350 mm Hg (Table 37.2). Large reductions in tubing length have been made possible by positioning the smaller new-generation pump consoles close to the patient and using mast mounted pumps to bring components closer together. The bioreactivity of blood coming into contact with artificial surfaces, such as tubing, is known to exacerbate the systemic inflammatory response and disrupt hemostasis. A major advancement has been the development of surface coatings that attempt to mimic the endothelial surface of blood vessels. These coatings have been shown to attenuate the increase of cytokines and inflammatory markers and preserve platelets.[32,33] When selecting tubing for the pediatric circuit, the goal is to safely achieve maximum blood flows, decrease prime volume, and attenuate blood trauma.

TABLE 37.2

Tubing Specifications and Maximum Blood Flow Ranges Tested at Children's Health Dallas

TUBING SPECIFICATIONS			CHILDREN'S HEALTH DALLAS PROTOCOL	
Internal Diameter (inches)	mL/ft	mL/rev	Max Art Flow (mL/min)	Max Gravity Drainage (mL/min)
1/8	2.5	3.5	~450	
5/32	3.7	5	~750	
3/16	5	7	~1300	500-650
1/4	9.65	13	~3000	1300-1500
5/16	13.5	18	~5500	2000-2200
3/8	21.71	27	>5000	4000-4500
7/16	28.5	38		5000-5500
1/2	38.61	45		>5000
5/8	55.77	65		

Hemoconcentrators

A hemoconcentrator is an ultrafiltration device that consists of semipermeable membrane fibers that remove plasma water and solutes. They function similarly to hemodialysis units but are simpler in that they do not require a dialysate solution. Blood flows through microporous membrane fibers, and since the hydrostatic pressure is higher inside the membrane fibers, effluent fluid permeates the membrane and can be removed. The membrane pore sizes are typically less than 55,000 daltons, which preserve plasma proteins such as albumin (65,000 daltons), and maintain the colloid oncotic pressure. The ultrafiltration rate of a hemoconcentrator is dependent on the hydrostatic pressure gradient across the membrane, blood flow rate through the membrane fibers, membrane pore size, and the hematocrit. Ultrafiltration is useful for increasing hematocrit, reducing high potassium levels after cardioplegia delivery, and removing harmful inflammatory mediators. Hemodilution during pediatric CPB is difficult to avoid, and a 2004 survey of pediatric cardiac surgery centers report that 98% of perfusionists routinely use a hemoconcentrator during the conduct of CPB.[20]

Circuit Prime

The CPB circuit is primed with a crystalloid replacement fluid. Common solutions include Plasma-Lyte A, lactated Ringer, and Normosol-R.[34] Lactated Ringer is a replacement fluid that contains 29 mEq/L of lactate but lacks magnesium. Plasma-Lyte A and Normosol-R both closely mimic human physiologic plasma electrolyte concentrations, osmolality, and pH. However, these two solutions do not contain calcium. At Children's Health Dallas, the perfusionists use Plasma-Lyte A because it does not contain lactate or calcium, thus allowing the perfusionists to lower CPB perfusate calcium levels, which is desirable, as is discussed later.

Once the CPB circuit is primed with a crystalloid solution and cleared of any air, the total prime volume of the circuit is estimated. The perfusionist must then choose between initiating CPB with or without adding heterologous blood. Unlike the adult patient population, blood products are often added to the neonatal and pediatric CPB circuits due to the small patient blood volume-to-circuit prime volume ratio. The dilutional effect of the crystalloid prime is determined by calculating the patient resultant hematocrit (HCTr). The HCTr formula, HCTr = (Patient blood volume × HCT)/(Patient blood volume + Circuit prime volume), is calculated once the patient hematocrit value is measured in the operating room before surgery. The institutional protocol at Children's Health Dallas is to maintain a CPB HCTr above 30%. If that value cannot be reached, then packed red blood cells (PRBCs) are added to the

circuit. The institutional protocol also directs that a half unit of fresh frozen plasma, approximately 100 mL, will be added to the circuit prime for all patients less than 6 kg.

The pre-CPB circuit prime drug additives at our institution include heparin (1000 units/mL), 8.4% sodium bicarbonate, 20% mannitol, furosemide (10 mg/mL), methylprednisolone, tranexamic acid, and 25% albumin (Table 37.3). The ideal prime solution should be "physiologic" and also attempt to attenuate the adverse response to artificially supporting a patient with an extracorporeal circuit.

TABLE 37.3

Cardiopulmonary Bypass Circuit Prime Drugs

Drug	Action	Prime Dose
Heparin	Anticoagulant	Calculated by Medtronic HMS and varies per patient
Sodium bicarbonate	Buffer	Achieve pH 7.40
Mannitol	Osmotic diuretic; oxygen radical scavenger	0.5 mg/kg; 12.5 g max dose
Furosemide	Loop diuretic	0.25 mg/kg; 20 mg max dose
Methylprednisolone	Corticosteroid	30 mg/kg; 1 g max dose
25% Albumin	Plasma protein	10% circuit prime volume
Tranexamic acid	Antifibrinolytic	20 mg/kg; 20 g max dose

Anticoagulation

Due to the foreign surface contact and resultant intrinsic activation of the coagulation cascade, the patient must be anticoagulated before CPB. Heparin is the most widely used anticoagulant during CPB, and it acts by super-activating antithrombin III (ATIII), which then inactivates thrombin and other proteases involved in coagulation. Heparin is used because it is fast-acting, and anticoagulation reversal can easily be achieved by administering protamine. Anticoagulation helps prevent circuit thrombus formation and avoid the devastating effects of potential arterial thromboembolism. Heparin was the anticoagulant used during Dr. Gibbon's first successful cardiac surgery in 1953, and its use during CPB has continued for more than 60 years. Before heparin administration and dosing protocols were available, anticoagulation methods were cumbersome and unsafe. The dosing was empiric, and the only methods for testing heparinization were lengthy laboratory heparin concentration tests. Fortunately, the activated clotting time (ACT) test was introduced in 1966 and this bedside whole blood test became the foundation of how heparinization is monitored in the cardiac operating room today.[35] Traditional laboratory tests such as partial thromboplastin time (PTT) and prothrombin (PT) time are sensitive to low doses of heparin and therefore are not useful during CPB. The ACT is a point-of-care test that measures the time (in seconds) needed for activated whole blood to form thrombin. In 1975, Bull et al.[36] reported a heparin management approach using the ACT test and the technique quickly became universally accepted. The report describes the heparin dose response curve technique and suggests an optimal ACT range of 480 seconds during CPB. In this technique, ACTs are run on various whole blood samples containing different heparin concentrations and results are plotted versus the heparin concentration. The heparin dose response curve, commonly referred to as the *Bull curve,* demonstrates the individualized ACT response to different levels of heparinization and is a useful tool in estimating the concentration of heparin necessary to achieve an ACT of 480

seconds (Fig. 37.6). Maintaining ACT results of at least 480 seconds during CPB remains the standard of care today. Though most clinicians will agree that 480 seconds is acceptable during CPB, there is debate whether or not that value should be universally applied, considering that not all ACT analyzers operate and activate blood in exactly the same manner.

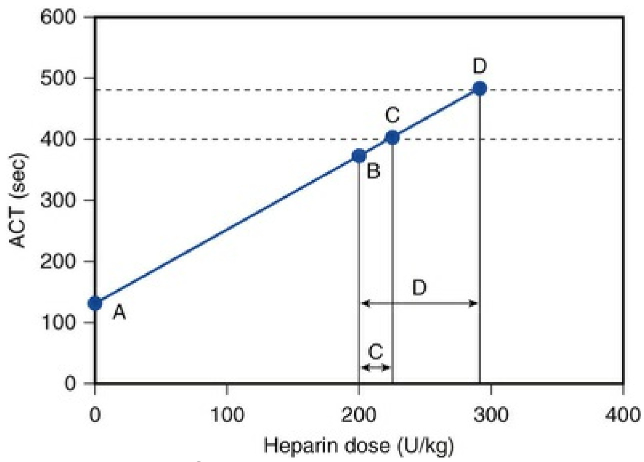

FIG. 37.6 An example of a heparin dose response curve wherein the patients baseline activated clotting time (ACT) is shown at point A. An initial heparin dose of 200 units per kilogram resulted in an ACT shown at point B. A linear extension of points A and B is drawn with an intersection at 400 (point C) and 480 seconds (point D), and these target intersects can be used to estimate further heparin doses to administer to the patient. (From Bull BS, Huse WM, Brauer FS, Korpman RA. Heparin therapy during extracorporeal circulation. II. The use of a dose-response curve to individualize heparin and protamine dosage. J Thorac Cardiovasc Surg. 1975;69:685-689.)

Pediatric patients undergoing cardiac repair suffer disproportionate postoperative bleeding complications after CPB, likely because of their size and immature coagulation system. Contributing factors to postoperative bleeding are dilution of coagulation factors during CPB, induction of the systemic inflammatory response, hematologic changes in cyanotic patients, hypothermia, and numerous coagulation factor deficiencies. All of these situations can inhibit adequate anticoagulation with heparin and ultimately lead to the generation of thrombin. It has been shown that prolonged ACT results of pediatric patients poorly correlate with the plasma levels of heparin during CPB.[37] Reports have shown that pediatric patients require higher plasma heparin concentrations than adults because they metabolize heparin faster, have a larger blood volume-to-body weight ratio, and have lower ATIII levels.[38,39] Weight-based heparin doses and ACT monitoring used with adult patients are therefore not recommended for use in pediatric patients.

The potential variability of a pediatric patient's response to heparin necessitates an individual dosing regimen and the use of different coagulation tests. A useful bedside hemostasis management tool in pediatric cardiac surgery is the Hepcon HMS PLUS (Medtronic Inc., Minneapolis, Minnesota, USA). The Hepcon HMS PLUS is fully automated and is used to run the following tests: ACT, heparin dose response (HDR) to identify individual heparin needs, and heparin-protamine titration (HPT) to verify heparin concentration. A baseline sample is collected from

the arterial line before heparinization and is used to test the HDR. The HDR test determines the baseline ACT and patient response to increasing amounts of heparin. Results are used to identify heparin-resistant or heparin-sensitive patients and determine the patient heparin concentration needed to achieve appropriate anticoagulation. To test the blood heparin concentration with the HPT test, blood is added to tubes containing different mg/mL concentrations of protamine. Heparin and protamine bind in a 1 : 1 ratio, so the tube that produces a clot can be used to determine the unit/mL heparin concentration. The HPT test is used frequently during CPB to maintain heparin concentrations suggested by the HDR and also run post CPB to verify proper heparin reversal after protamine administration. Without heparinization, hemodilution and the degree of hypothermia alone could extend the ACT beyond 480 seconds and this effect is amplified in the pediatric patient. Administering heparin to maintain a patient heparin concentration calculated by the HDR, despite an ACT above 480, will help to reduce consumptive coagulopathy, thrombin generation, fibrinolysis, neutrophil activation, and the need for transfusions.[40,41]

Once the patient is ready to be cannulated for CPB, a heparin bolus is administered to the patient by the anesthesiologist into an intravenous line or by the surgeon directly into the right atrium. In general, the patient receives a 400 U/kg dose of heparin minutes before arterial cannulation. Once the heparin has circulated within the patient for approximately 5 minutes, a blood sample from an arterial or intravenous line is used to run an ACT and HPT. If the ACT reaches 480 seconds or the HPT confirms an adequate heparin concentration, cardiotomy pump suction may be used and CPB may be initiated when the surgeon inserts the arterial and venous cannulas. ACT and HPT tests are run every 30 minutes during CPB, and heparin is administered if the ACT falls below 480 seconds or the heparin concentration falls below the maintenance value calculated by the HDR. If a parameter is low, the Hepcon HMS PLUS uses a formula based on the HDR, blood volume of the patient, and circuit prime volume to calculate the amount of heparin needed to adequately raise the ACT or HPT.

Cannulation

Cannulation refers to the process in which the surgeon attaches the venous limb of the CPB circuit to the systemic venous circulation of the patient, while attaching the arterial limb to the systemic arterial system of the patient. This is most commonly accomplished by placing an arterial cannula in the distal ascending aorta and venous cannulas in the SVC and IVC, respectively. The cannulas are inserted through appropriately sized purse-string sutures and secured with tourniquets. This bicaval configuration allows for the achievement of “total” CPB, and the vast majority of cardiac repairs can be accomplished using this technique. In pediatric cardiac programs, patients ranging in weight from approximately 1000 gm up to adulthood are placed on CPB. Therefore a wide range of cannula sizes must be kept in stock. Arterial cannulas range from as small as 8 French (Fr) (2.67 mm) in diameter up to over 20 Fr. Venous cannulas for CPB are available in straight and angled varieties and range down to as small as 10 Fr. Inserting these cannulas into the diminutive aorta and vena cavae of neonates is a taxing technical exercise that must be accomplished without complication in order to appropriately support the patient

during the repair and leave the patient with undamaged vessels at the cannulation sites postoperatively.

Exceptions to standard bicaval cannulation are frequently seen in pediatric practice. First, patients can have anomalies of systemic venous return, such as bilateral superior vena cavae, ipsilateral hepatic veins, or interrupted inferior vena cava with azygous continuation to the SVC. All these anomalies have to be assessed, and an appropriate venous cannulation strategy must be devised. Occasionally, if these anomalies are prohibitive for selective cannulation, or the overall patient size is so small that the cavae are too small to cannulate, the right atrial appendage is cannulated in isolation, and periods of circulatory arrest, wherein venous return is not required, are used as to accomplish intracardiac portions of the repair.

Alternatives to standard ascending aortic cannulation are also used. In order to accomplish aortic arch reconstructions without resorting to circulatory arrest, a small prosthetic vascular tube graft is anastomosed to the innominate artery and the arterial cannula is inserted into this “chimney” graft. Alternatively, if the patient is large enough, the innominate artery can be cannulated directly. These innominate artery cannulation techniques allow the brain to be perfused up the right carotid artery while the aortic arch is being repaired.

Reoperations are common in congenital heart surgery. A number of these patients have pulmonary outflow conduits that are densely adherent to the sternum. Patients with transposition of the great arteries have an abnormally anteriorly located ascending aorta that can also be adherent to the chest wall in the midline. Peripheral cannulation via a femoral artery is sometimes necessary in these instances. Peripheral arterial cannulation in children should only be performed when absolutely necessary and converted to the ascending aorta as soon as possible. The obturation of the femoral artery by the cannula almost always causes hypoperfusion of the lower extremity. With longer cannulation times, the leg can be at significant risk for ischemic complications.

Cardiopulmonary Bypass

Pediatric Versus Adult Considerations

Although many of the management techniques governing pediatric and adult CPB are similar, several differences do exist (Table 37.4). The small size of the pediatric patient and nature of the surgical repair often expose these patients to moderate or deep hypothermic temperatures, wide ranges of perfusion flow rates, and hemodilution. These management techniques represent extreme shifts from normal physiologic parameters, and the harmful effects are potentially more pronounced in these small patients. Low-flow perfusion or circulatory arrest at deep hypothermia(15°C–20°C) is often required because of the complexity of the repair, significant aortopulmonary collateral blood flow returning to the operative field from the pulmonary veins, or simply because position of the perfusion cannulas interferes with access to the surgical site.

TABLE 37.4

Differences Between Adult and Pediatric Cardiopulmonary Bypass

Parameter	Adult	Pediatric
Hypothermic temperature	Rarely below 25°C-32°C	Commonly 15°C-20°C
Use of circulatory arrest	Rare	Common
Pump prime		
Dilution effects on blood volume	25%-33%	150%-300%
Additional additives		Blood, albumin
Perfusion pressures	50-80 mm Hg	25-50 mm Hg
Influence of α-stat versus pH-stat management strategy	Minimal at moderate hypothermia	Marked at deep hypothermia
Measured $PaCO_2$ differences	30-45 mm Hg	20-80 mm Hg
Glucose regulation		
Hypoglycemia	Rare—requires significant hepatic injury	Common—reduced hepatic glycogen stores
Hyperglycemia	Frequent—generally easily controlled with insulin	Less common—rebound hypoglycemia may occur

From Greely WJ, Cripe CC, Nathan AT. Anesthesia for pediatric cardiac surgery. In: Miller RD, Cohen NH, Eriksson LI, et al. Miller's Anesthesia. 8th ed. Philadelphia: Elsevier Saunders; 2015:2820.

Compared with adults, hemodilution of the pediatric patient during CPB has a larger impact on the concentration of blood components, and the blood-to-foreign surface area exposure is much greater. This relatively greater exposure to nonendothelialized surfaces can lead to an increased inflammatory response and damage the formed elements of blood. Another important contrast between pediatric and adult support involves calcium management. The immature myocardium is susceptible to exacerbated postischemic injury due to overly rapid calcium “loading” at reperfusion.[42,43] Because of this, at Children's Health Dallas a perfusate that is relatively depleted of calcium is used until well after cross-clamp removal. Calcium is restored in a stepwise fashion before weaning from the circuit. The coagulation system of neonates and infants also differs from adults in that they have quantitative deficiencies of coagulation factors at baseline. These deficiencies of the immature coagulation system coupled with hemodilution discussed earlier result in significant postoperative coagulopathies and anemia that must be addressed with blood products much more commonly than in adult cases.

Initiation of Cardiopulmonary Bypass

Before starting a planned operation, the surgical team will discuss the procedure and form a detailed management plan for each team member. The perfusionist must understand the type and complexity of the surgery and discuss the proper cannula section, degree of hypothermia, myocardial protection technique, and any other unique patient variables that might affect perfusion management. The fundamental concepts of managing CPB for congenital patients are similar to adults, but anatomic variations and physiologic extremes complicate the approach. Once the surgical plan is established, the patient is prepped and draped for the skin incision and sternotomy. With the chest open, the surgeon exposes the heart and major vessels and then directs the anesthesiologist to administer heparin before cannulation. Alternatively, the surgeon can administer the heparin directly to the right atrium. Next, the arterial and venous cannulas are inserted, but before it is safe to initiate CPB, it is important to confirm an adequate anticoagulation level by obtaining an ACT and heparin concentration and that the arterial cannula is unobstructed. Congenital patients, especially cyanotic patients, often demonstrate variable dose responses to heparin. In addition, it cannot be assumed that the CPB dose of heparin is circulating in the patient, as intravenous line malfunction can occur. Initiating CPB

on a pediatric patient with an obstructed aortic cannula could quickly exsanguinate the patient, as venous drainage commences without return of this blood to the patient, and cause severe hypotension. Once these two safety checks are complete, the patient is ready for CPB.

The venous line is unclamped to siphon deoxygenated blood from the patient, and the arterial flow is slowly increased as the heart begins to empty. Bicaval cannulation is often used in congenital surgery, but it is common to initiate CPB with only one cannula. This is done to verify adequate drainage from one cannula, as it would be difficult diagnose poor drainage from a single cannula if both were open. Once both cannulas are open, adequate venous drainage is confirmed when the central venous pressure (CVP) falls to zero and the SVC, IVC, and right atrium are collapsed. Total (also termed *full* or *complete*) CPB is achieved when all of the systemic venous blood is being diverted to the heart lung machine and full arterial flow can be achieved. When on total CPB, the mean arterial pressure (MAP) and CVP should confirm that the heart is empty by showing a flat tracing. However, the many anatomic variations of the congenital patient can lead to blood returning to the heart despite adequate drainage. Variations such as a patent ductus arteriosus, major aortopulmonary collateral arteries, an unrecognized left SVC draining to the coronary sinus, and aortic insufficiency can return blood to the heart and should be considered when evaluating venous drainage. Assessment of adequate venous drainage and perfusion flow rate is critical before proceeding to the surgical repair. A poorly positioned venous or arterial cannula can restrict optimal perfusion flow and addressing this issue during the aortic cross-clamp period would waste unnecessary myocardial ischemic time. Once cannula placement is deemed acceptable, full perfusion flow is achieved, and oxygenation from the oxygenator is confirmed, the anesthesiologist can turn off the ventilator.

Determining and Monitoring Effective Perfusion Flow Rate

The fundamental goals of bypass are to meet the metabolic demands of all tissues and to attenuate the deleterious pathophysiologic effects of artificially supporting a patient. Once the patient is transitioned to cardiopulmonary bypass, several management techniques are used to safely optimize the level of support. Perfusion flow rate, which represents the cardiac output during CPB, is altered to meet the oxygen consumption needs of the patient. Global adequacy of flow is estimated in real time by the display of oxygen saturation by a sensor in the venous return line. Assessing regional oxygen consumption to the brain, kidneys, or bowel, for instance, is a challenge. Additionally, due to age-related differences of body surface area (BSA)-to-blood volume ratios, flow rate indexes are higher in neonates than adults. The optimal effective flow rate or cardiac index for any size patient remains unclear; however, recommended flow ranges at normothermia are listed in Table 37.5. Considering that the perfusion flow rate is not fixed during the different phases of CPB, several variables are helpful in determining a safe minimal rate. Initial normothermic target rates are calculated for CPB initiation by weight and BSA. At Children's Health Dallas, in addition to the CPB initiation flow rates calculated by weight, the perfusionist calculates several cardiac indexes ranging from 2.4–3.0 L/min/m^2. Factors such as the degree of hypothermia, acid-base balance, depth of

anesthesia and neuromuscular blockade, hematocrit, venous saturation, lactate level, urine output, and near infrared saturation trends are used to guide perfusion flow rates. Patient temperature is the greatest factor affecting perfusion flow, and rates as low as 40–50 mL/kg are routinely used at core temperatures in the 20°C range.

TABLE 37.5

Recommended Pump Flow Rates at Normothermia

Patient Weight (kg)	Pump Flow Rate (mL/kg/min)
<3	150-200
3-10	125-175
10-15	120-150
15-30	100-120
30-50	75-100
>50	50-75

Arterial Pressure

The MAP will slowly lose its pulsatile trace and flatten out as the heart empties on CPB. Though the MAP is calculated by factoring the systolic and diastolic pressures, the value of the flat tracing is referred to as the MAP and perfusion pressure during CPB. The transition to CPB often leads to hypotension, and in contrast to adult cases, vasopressors (eg, phenylephrine) are not typically administered in the early phase of CPB in young patients. The goal in the early phase of CPB is to cool the patient and reduce the metabolic demands. Low perfusion pressure, 20–30 mm Hg, is accepted during the cooling phase, and vasodilators (eg, phentolamine) are actually used to reduce arterial tone and increase uniformity of perfusion and improve cooling. Vasodilation has been shown to improve temperature distribution and reduce lactate production in pediatric deep hypothermic CPB.[44] Hemodilution, hypocalcemia, and the inflammatory response are also factors that cause hypotension at the onset of CPB. Hemodilution will lower the perfusion pressure because of the viscosity reduction, and hemoconcentration performed by the perfusionist with the hemoconcentrator can easily increase perfusion pressure by raising the hematocrit. The systemic inflammatory response is triggered by the foreign surface contact of blood and bypass circuitry. This response releases many vasoactive mediators, which can quickly drop the perfusion pressure, and highlights the importance of minimizing circuit surface area for the pediatric patient. The decrease in pressure in an adult patient with coronary or carotid stenosis would likely be treated with a vasopressor, while increasing perfusion flow is the preferred method in young patients.

Arterial and Venous Oxygen Saturation

Most oxygen saturation monitoring techniques are noninvasive and inexpensive and can be used in real time. Changing perfusion flow rate and oxygen delivery will have immediate and direct effects on oxygen saturation levels. Pulse oximetry is a clinical mainstay and is used to monitor oxygen delivery to the extremities during the preoperative and postoperative periods. However, due to the nonpulsatile flow

pattern generated during CPB, this technology is ineffective.

As mentioned earlier, a mainstay monitoring technique during CPB is to track the oxygen saturation of the venous line blood draining into the venous reservoir. As a general guideline, perfusion flow rate is adjusted to maintain this mixed venous saturation (SvO_2) greater than 70%. While this guideline is helpful during "normal" physiologic conditions, the many nonphysiologic variables of CPB cause shifts in the oxyhemoglobin dissociation curve (Fig. 37.7), and these venous oxygen saturations may fail to represent satisfactory oxygen delivery to the tissues. Leftward shifts in the curve prevent oxygen from being released from hemoglobin, which could deceivingly demonstrate an acceptable SvO_2 in the presence of tissue hypoxia. As the patient is cooled during CPB, regional deoxygenation has been shown to occur despite a normal or rising SvO_2 without increasing perfusion flow rate.[45] Hypothermia not only strengthens the hemoglobin oxygen affinity but also creates an alkaline blood pH and causes a further leftward oxyhemoglobin shift. In this situation, it is important to cool and warm patients methodically to minimize the temperature gradient between the blood and tissues and maintain perfusion flow so that the SvO_2 does not trend downward. As tissue temperature decreases, venous line SvO_2 can be used to help guide the reduction of perfusion flow rate.

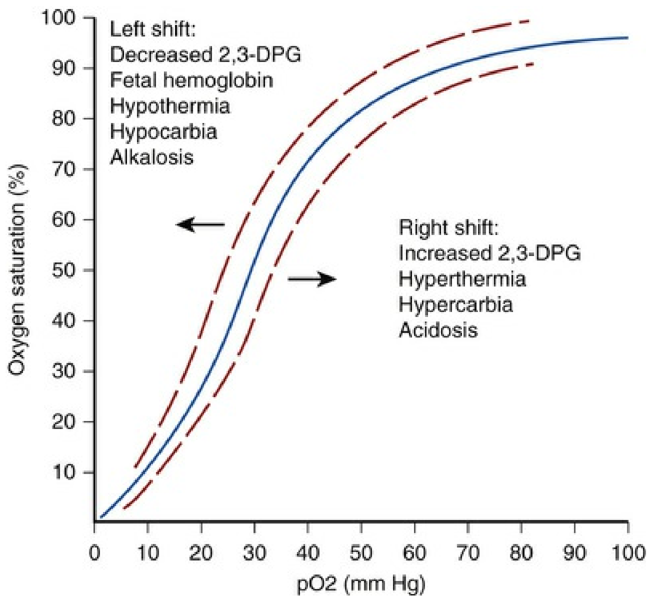

FIG. 37.7 The oxyhemoglobin dissociation curve.

It is especially critical to meet the metabolic needs of brain tissue, and global SvO_2 values may misrepresent regional oxygen consumption. It has been shown that considerable regional differences exist and SvO_2 can overestimate regional saturations from the brain.[46] The majority of venous blood analyzed by the venous line SvO_2 comes from IVC cannula, and IVC saturation is notoriously misleading as an estimate of oxygen consumption due to "contamination" by highly saturated renal venous blood. Though the SvO_2 does have its place in guiding perfusion flow rate, more specific, regional oxygenation assessment is currently recommended to ensure adequate perfusion flow distribution, particularly for the brain.

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) is a noninvasive optical sensor that can measure cerebral and somatic tissue oxygenation. NIRS monitoring is gaining considerable popularity because sensor pads may be placed over various regional tissue beds, particularly both cerebral hemispheres, and display real-time results. Somatic monitoring sites such as flank, abdominal, and muscle are suggested to help broaden the assessment of systemic hypoperfusion. The technology works by bouncing various wavelength arcs of near-infrared light from a sensor emitter and detector. These photodetectors allow for selective measurement of tissue oxygenation. This technology is widely used in the operating room and ICU, although interpreting the results has been a topic of debate. A validation study performed at Children's Health Dallas demonstrated that cerebral NIRS values accurately predicted the oxygen saturation in the SVC on CPB and that flank NIRS values were significantly associated with IVC saturation.[47] As increasing evidence validates tissue oximetry against invasive measurements, NIRS monitoring has shown its value in quickly detecting regional low flow.[48-51] At Children's Health Dallas, the perfusionists use NIRS trends and values to guide perfusion flow rate, hematocrit, blood gas strategy, temperature, and vasomotor tone (Box 37.1). It is important to note that NIRS helps to guide rather than dictate perfusion management. The upper limits and critical lower values reported by NIRS are poorly defined.

Box 37.1

Methods to Improve Cerebral Near-Infrared Spectroscopy Values

Increase perfusion flow rate

Increase hematocrit

pH-stat blood gas strategy

Decrease temperature

Increase mean arterial pressure; vasopressor

Verify adequate superior vena cava drainage

Considering the regional venous oxygen saturation variations of the neonatal and infant cardiac surgical patients, NIRS provides valuable information and early detection of poor perfusion in critical organs. NIRS has been particularly useful as a real-time monitor on patients with hypoplastic left heart syndrome, for example. Cerebral oxygen saturation measured after stage I palliation has been shown to strongly correlate with hemodynamic parameters and help to identify early postoperative complications.[49,52] Hoffman et al.[53] found that avoiding cerebral hypoxia with the use of NIRS monitoring was the most significant factor in improving childhood neurodevelopmental outcomes.

Methods to Optimize Physiologic Management

Target Hematocrit and Ultrafiltration

Despite the progress of reducing the pediatric circuit prime volume, hemodilution during CPB remains difficult to avoid.[54] Hemodilution can cause edema, coagulopathy, blood and colloid osmotic pressure reduction, and the need to transfuse blood products. Blood product transfusion is the most straightforward solution to address these complications; however, the risk-benefit assessment of blood transfusion must be considered. Transfusion-related complications include increased postoperative morbidity and mortality, prolonged mechanical ventilation and hospital stay, exacerbation of the inflammatory response, and infection.[55-58] Modern blood bank testing and donor screening have significantly reduced infectious complications, but noninfectious risk remains a major concern. In addition, smaller patients are exposed to a higher transfusion risk because the transfusion effects may be more pronounced than in adult patients. With a goal of minimizing hemodilution and donor blood exposure, the cardiac team must implement a transfusion algorithm and define a target hematocrit during CPB. Perioperative and developmental outcomes data reported from clinical trials at the Boston Children's Hospital demonstrate that, when compared with target CPB hematocrit values of 30%, hematocrit values at or below 20% are associated with adverse outcomes and that the benefits of hematocrit values higher than 25% should be further investigated.[59,60] The protocol at Children's Health Dallas is to maintain a hematocrit of at least 30% during cardiopulmonary bypass.

Reducing circuit prime volume and incorporating an ultrafiltration device can significantly reduce donor blood exposure. Originally, a hemoconcentrator added to the CPB circuit was used primarily to remove plasma water and raise the hematocrit. This process is referred to as “conventional ultrafiltration” (CUF) and its initial use was met with a few limitations. Perfusionists were accustomed to using diuretics to help increase the hematocrit; however, this strategy offered little control and required adequate kidney perfusion during CPB. When ultrafiltration emerged as a CPB technique in the mid-1980s, hemoconcentrators were viewed as an expensive option for removing excess circuit volume. Also, while fluid is removed from the circuit during CUF, the volume in the venous reservoir level diminishes and CUF must be stopped before the reservoir is emptied, which would have catastrophic consequences. Thus the amount of fluid removed during CUF is dependent on available volume in the venous reservoir, which limits the ability to effectively raise the hematocrit. In 1991 a report described a *modified ultrafiltration* (MUF) technique performed after weaning the patient from CPB and enabled the perfusionist to concentrate the entire circuit and return most of that volume back to the patient.[61] During this era, pediatric circuit prime volume was still rather high and various MUF techniques proved to be a valuable resource for reducing total body water post CPB. The popularity of MUF led investigators to explore the potential reduction of proinflammatory mediators during ultrafiltration. An additional ultrafiltration technique, *zero balance ultrafiltration* (ZBUF), emerged as alternate method to attenuate the inflammatory response. ZBUF is performed by removing the ultrafiltration effluent from the circuit during CPB while administering a replacement solution (eg, Plasma-Lyte A) to the venous reservoir in a 1 : 1 ratio. The high-volume filtration of fluid that is able to be exchanged allows the perfusionist to

control electrolyte and glucose levels (eg, high potassium levels after delivering cardioplegia) and more effectively remove inflammatory mediators. The increasing acceptance of ultrafiltration during CPB led to developing many technique variations during the preoperative, perioperative, and postoperative phases and can thus be categorized into two groups: blood concentration and blood filtration.

In preparation for neonatal CPB at Children's Health Dallas, for example, the perfusionist adds approximately 300 mL of packed red blood cells to the venous reservoir after priming the circuit with Plasma-Lyte A. The circuit volume is recirculated through the hemoconcentrator, and volume is removed until the reservoir is almost empty. The circuit prime is then "washed" by adding approximately 500 mL of Plasma-Lyte A and then removing that volume. This process is known as *prebypass ultrafiltration* (Pre-BUF), and in addition to concentrating the circuit, Pre-BUF has been shown to reduce high potassium, glucose, lactate, citrate, and bradykinin levels found in packed red blood cells. CUF is then performed during the early phase of CPB to remove any excess circuit volume and maintain a hematocrit of 30%. During the warming phase of CPB the perfusionist performs CUF and ZBUF. This combined ultrafiltration strategy, coupled with a miniaturized circuit, allows the perfusionist to filter the blood and exceed or meet baseline hematocrit values before weaning from CPB.

Hypothermia

DHCA versus SCP

The therapeutic potential of hypothermia has been known for centuries and has been routinely used in cardiac surgery since its inception. This concept relies on the fundamental physiologic relationship between oxygen consumption and temperature. In 1950, Bigelow and colleagues[62] compared the use of normothermia and topical cooling on dogs and reported superior ischemic tolerance by surface cooling after 15 minutes of circulatory arrest. The first clinical application in cardiac surgery was reported 1953 by Lewis and Taufic, who described the successful repair of an ASD in a 5-year-old girl using topical cooling and total body hypothermia.[2] To achieve this, patients were submerged in an ice bath to reduce their temperature to approximately 28°C, and then the defect was closed with the aid of inflow occlusion. In 1958, Sealy and colleagues[63] successfully reported the use of hypothermia in conjunction with CPB. The use of CPB with various degrees of hypothermia or deep hypothermic circulatory arrest (DHCA) dramatically increased the "safe" period of support, which enabled surgeons to repair increasingly complex anomalies, and allowed cardiac surgery to flourish.

Hypothermia suppresses metabolic activity, preserves high energy phosphate stores, and reduces the reaction rate of biochemical reactions. Several factors are used in determining the type and degree of hypothermia during CPB. The most significant factor is the degree of surgical difficulty and anticipated CPB support time. Complex surgical repairs requiring lengthy support times would benefit from more pronounced hypothermia. The degree of hypothermia varies greatly and is typically classified as mild, moderate, deep, and profound hypothermia (Table 37.6). Deep hypothermia might be seen as desirable when low flow (≤50 mL/kg/min) or DHCA is desired, as is the case in operations involving complete aortic arch reconstruction. Circulatory arrest is a process in which the perfusion flow is turned

off and the patient's blood volume is allowed to drain into the venous reservoir. This dramatic application provides an asanguineous and completely motionless surgical field, facilitating complex repairs. In very small patients, the venous cannula may be obstructive and DHCA is required in order to remove the cannula and access the surgical site. Hypothermia also facilitates exposure of the surgical field by allowing decreased perfusion flow rates, which reduces the amount of collateral blood returning to the heart via the pulmonary veins (Fig. 37.8). Patients with pulmonary blood flow restrictions (eg, tetralogy of Fallot, pulmonary atresia) can develop major aortopulmonary collateral arteries, and these collaterals can flood the heart during the aortic cross-clamp period if CPB flow is maintained. This excessive blood return not only obscures the surgical site but may also warm the cold arrested myocardium or wash out cardioplegia from the coronary arteries. Hypothermia and perfusion flow rate reduction can attenuate this collateral flow while maintaining adequate oxygenation delivery to the patient.

TABLE 37.6

Hypothermia Classifications in Cardiac Surgery

Category	Core Temperature
Mild	32-34°C
Moderate	25-32°C
Deep	15-25°C
Profound	≤15°C

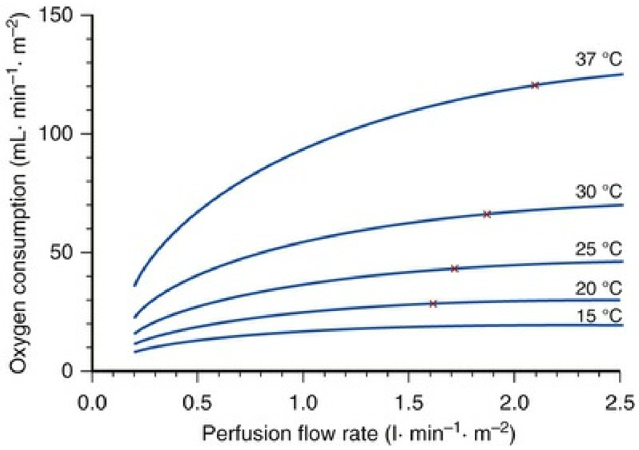

FIG. 37.8 Nomogram relating oxygen consumption (VO_2) to perfusion flow rate and temperature. (From Kirklin JW, Barratt-Boyes BG. Hypothermia, circulatory arrest, and cardiopulmonary bypass. In: Kirklin JW, Barratt-Boyes BG, eds. Cardiac Surgery. 2nd ed. New York, NY: Churchill-Livingstone; 1993:91.)

The rate of cooling varies greatly between different tissue beds; thus multiple measurement sites are recommended to ensure uniform cooling distribution (Fig. 37.9). The optimal temperature measurement site is controversial, but choosing sites that closely reflect tissue temperatures of vital organs, particularly the brain, is widely accepted. At Children's Health Dallas, the patient's nasopharyngeal, rectal, and bladder temperatures are monitored during surgery. Nasopharyngeal closely correlates with brain temperature; however, it may underestimate the global core

temperature considering the slower cooling rates of other tissue beds. For this reason, rectal and bladder temperature monitoring sites with slower rates of cooling are typically used to guide cooling end points.

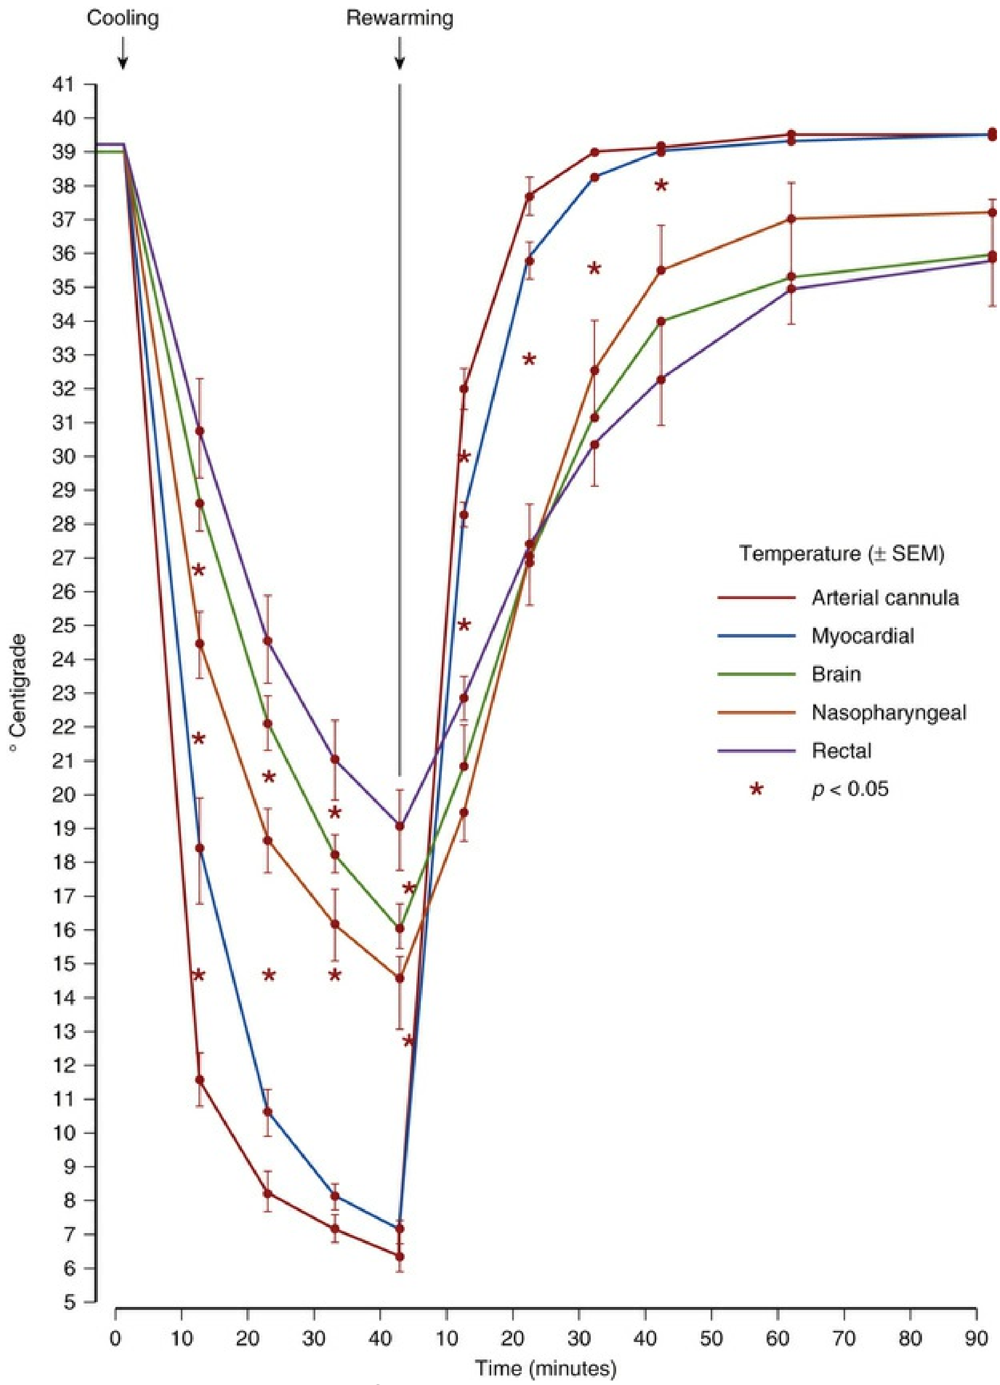

FIG. 37.9 Relationships of temperatures measured at various sites over time during cooling and warming from cardiopulmonary bypass. (From Stefaniszyn HJ, Novick RJ, Keith FM, et al. Is the brain adequately cooled during deep hypothermic cardiopulmonary bypass? Curr Surg 1983;40:294-297.)

The concept of a "safe" circulatory arrest time is controversial, and most guidelines are met with a degree of uncertainty. A nomogram focused on neurologic

protection has been devised that estimates “safe” circulatory arrest times, but values should not be used as absolutes (Fig. 37.10). The historic incidence of perioperative cerebral injury during DHCA has led investigators to explore alternative techniques to protect the brain during complex repairs. Antegrade cerebral perfusion (ACP, also known as selective cerebral perfusion) uses a cannulation technique that directs perfusion flow to only the brain with the theoretic advantage of protecting it from hypoxic ischemic injury. Though this technique has been adopted among many surgical centers, investigations comparing DHCA and ACP have failed to definitively demonstrate superiority of either technique[64-66] and not all of this work is focused only on neurologic issues. Recent literature has suggested that during ACP, the resultant partial perfusion from collateral vessels provides better protection to abdominal organs than DHCA.[67,68] In addition, the ideal temperature during ACP remains unknown. Recent reports, however, have demonstrated superior results using moderate to mild hypothermia, in the 25°C–30°C range, rather than deep levels of hypothermia.[69,70] Considering the coagulopathy, inflammatory response, as well as the vascular and organ dysfunction associated with deep hypothermia, a lesser degree of hypothermia may provide superior clinical outcomes.

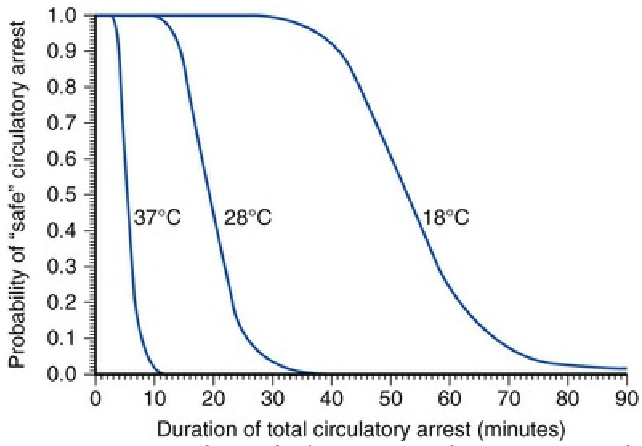

FIG. 37.10 Probability of a safe (absence of structural or functional damage) circulatory arrest according to duration. Estimate at nasopharyngeal temperatures of 37°C, 28°C, and 18°C. (From Kirklin JW, Barratt-Boyes BG. Hypothermia, circulatory arrest, and cardiopulmonary bypass. In: Kirklin JW, Barratt-Boyes BG, eds. Cardiac Surgery. 2nd ed. New York, NY: Churchill-Livingstone; 1993:74.)

pH and $PaCO_2$ Strategy

CO_2 concentration and pH are primary determinants of cerebral blood flow. As body temperature decreases, the solubility of CO_2 increases, resulting in a decreased $PaCO_2$ and increased pH. Manipulating the acid-base management during hypothermic bypass can be classified by two mechanisms of control: alpha-stat or pH-stat. Both mechanisms have been studied intensely in reptiles (ectotherms) and hibernating mammals (endotherms), looking at their adaptive blood pH alterations that allow them to withstand extreme temperature fluctuations. pH-stat acid-base management is practiced by hibernating mammals and is accomplished by decreasing ventilatory rate and raising $PaCO_2$ while maintaining a constant pH

during hypothermic conditions. Maintaining pH, while varying temperature during hibernation, is thought to preserve oxygen stores by decreasing metabolic activity. Alternatively, reptiles use alpha-stat and allow their pH to enter an alkaline state by reducing $PaCO_2$.

The perfusionist can maintain a pH-stat or “temperature-corrected” acid-base strategy during CPB by allowing CO_2 to passively rise or actually adding CO_2 to the CPB circuit. Cerebral blood flow has been shown to decrease during hypothermia using the alpha-stat strategy and demonstrates a linear relationship to the increased $PaCO_2$ when a pH-stat strategy is used.[71] In addition to preserving cerebral blood flow during hypothermia, a pH-stat strategy induces a rightward shift of the oxyhemoglobin dissociation curve (see Fig. 37.7) potentially allowing for increased oxygen “off-loading” from hemoglobin at the capillary level.

Whether pH-stat or alpha-stat acid-base management during hypothermic CPB demonstrates clear benefits on clinical outcomes has been difficult to demonstrate. However, it is suggested that a pH-stat strategy is optimal for pediatric patients and alpha-stat is the optimal strategy on adult patients.[72]

Myocardial Protection

Myocardial protection refers to the strategies and techniques employed to allow for the surgeon to work on the heart in a bloodless and motionless field yet recover the best possible postischemic myocardial function and cardiac output for the patient. Strategies for both adults and children attempt to reduce the cardiac workload and minimize the metabolic demands and consequences of oxygen deprivation during ischemia. Reducing afterload and emptying the heart by initiating CPB is a myocardial protection technique during beating heart procedures (eg, palliative shunts, bidirectional Glenn procedure). When the heart needs to be stopped and opened for intracardiac repairs, the aorta is cross-clamped and cardioplegia is delivered to the coronary circulation to cause prolonged asystole. Cardioplegia is a myocardial arrest-producing solution that is formulated to prolong the myocardial tolerance to ischemia. There are many techniques to protect the myocardium, but cardioplegia strategies are often the focus when discussing protection techniques. In North America, high potassium depolarizing solutions are the most common type of cardioplegia used.[34] Universal agreement on an optimal myocardial protective technique is widely debated, and most strategies are guided by surgeon or institutional preference.

After the first successful cardiac surgical correction using CPB in 1953, surgeons explored a variety of techniques to support the patient during the repair. It did not take long for them to realize that the poor visibility in an open beating heart needed to be addressed. It was difficult to operate on a beating heart, and lethal air embolism (ie, air ejected out the aortic valve) claimed the lives of many patients. In 1955, Dr. Melrose and his colleagues[73] described a technique of stopping the heart to address these dangerous operative conditions. The report outlines how potassium citrate is used to achieve elective cardiac arrest. This sparked the interest of other investigators, and in 1958 Dr. Sealy and his colleagues at Duke reported an additive modification to the Melrose method and coined the term *cardioplegia*.[74] It is interesting to note that improving operative visibility, not protecting the heart, was the goal of arresting the heart. Further investigation began to show that these

techniques caused damage to the myocardium and cardioplegia was abandoned. In the 1960s and early 1970s a number of investigators tried to find an alternative protection technique. Reports of using direct coronary perfusion with intermittent aortic occlusion, topical hypothermia, and normothermic ischemia with aortic occlusion failed to achieve consistent results, presented major time limitations for surgeons, and myocardial damage remained an issue. The observation of "stone heart" by Dr. Cooley and his colleagues[74] highlighted the need to prioritize the protection of the myocardium, and they proposed that depleting myocardium ATP stores would leave the heart frozen in systole. Fortunately, several European researchers continued to explore cardioplegia solutions throughout the 1960s. They discovered that the chelating action of the citrate ion of the potassium-citrate solution was responsible for myocardial damage because it interferes with cellular calcium and magnesium traffic. This finding resparked interest into pharmacologic cardiac arrest around the world, with a new focus of protecting the myocardium by membrane stabilization and managing calcium and other ion shifts. During the 1970s, a sequence of landmark reports hailed the worldwide return of cardioplegia and its use in protecting the myocardium. These publications identified potassium-chloride as a safe arresting agent and, moreover, showed that cold cardioplegia significantly extends the safe ischemic period. The use of cardioplegia additives such as magnesium, procaine, lidocaine, mannitol, buffering agents, glucose, glutamate, and aspartate has led to much debate and a plethora of cardioplegia recipes. By the late 1970s, these crystalloid cardioplegia solutions became the dominant form of myocardial protection. A major shift occurred in 1978 when Dr. Buckberg and his group at the University of California, Los Angeles, suggested that blood was an optimal cardioplegia vehicle.[75] Blood cardioplegia was shown to be superior to a crystalloid cardioplegia solution because blood provides better oxygen delivery, effective buffering, free radical scavenging, and ideal oncotic pressure.[76] Effective myocardial protection has allowed surgeons to approach increasingly complex surgical corrections. A consequence of the motivation to optimize cardioplegia techniques has led to an incredible variation of myocardial protection techniques. Despite numerous advances and an extensive body of research, myocardial protection techniques continue to be largely program based because hard evidence, from prospective randomized trials, for instance, is lacking.[77]

A depolarizing cardioplegia solution uses a high dose of potassium, delivered to the coronary circulation in isolation, to decrease the cardiac membrane resting potential and arrest the heart in diastole. Delivering a cold dose of depolarizing cardioplegia does add a degree of protection, but simply arresting and cooling the heart does not offer optimal protection. An effective cardioplegia solution should (1) achieve quick arrest and minimize ATP depletion, (2) delay the onset of irreversible damage and limit reperfusion injury, (3) be reversible with prompt resumption of cardiac function upon washout, and (4) be nontoxic.[78] Efforts to optimize an effective cardioplegia solution have focused on myocyte calcium management and pH buffering. Modified depolarizing cardioplegia, a solution that combines a depolarizing agent with additional membrane stabilizing additives (eg, magnesium or lidocaine), has gained interest in attempting to optimize cardioplegia. A modified depolarizing solution that is gaining popularity in congenital surgery is del Nido cardioplegia (Compass; Baxter Healthcare Inc., Edison, New Jersey, USA) (Table 37.7).[79] Unlike most cardioplegia solutions that require frequent maintenance dosing

to achieve effect protection, del Nido cardioplegia is known to provide excellent myocardial protection without the need to frequently redose.[80] This reported advantage allows the surgeon to operate uninterrupted while reducing the aortic cross-clamp time. Custodiol HTK (Essential Pharmaceuticals, LLC, Newton, Pennsylvania, USA) is an intracellular cardioplegia that achieves electrical and mechanical arrest by equilibrating the intracellular and extracellular ion concentrations. This solution is also gaining popularity in the congenital patient population because it does not require frequent maintenance doses.

TABLE 37.7

Crystalloid Formula of del Nido Solution

Plasma-Lyte A*	1000 mL
K-Cl	26 mEq
Na-HCO_3 8.4%	13 mEq
Mannitol 25%	3.25 g
Lidocaine 2%	130 mg
Mg-SO_4 50%	2 g

*Baxter Healthcare Corporation, Deerfield, Illinois, USA.

At Children's Health Dallas, the surgical team uses del Nido cardioplegia with a customized pediatric cardioplegia circuit.[81] The cardioplegia is mixed at a 1 : 4 blood-to-crystalloid ratio, and upon aortic cross-clamp placement, a single, cold (4°C–6°C), 20 mL/kg antegrade dose is administered via the aortic root. Although there is no cardioplegia specifically designed for neonatal or congenital patients, several considerations are made to optimize protection. As previously discussed, tolerance of intracellular calcium shifts into the immature myocardium is impaired. The additives lidocaine and magnesium in del Nido cardioplegia both help to control intracellular calcium accumulation. Lidocaine prevents sodium shifts by blocking fast voltage sodium channels, which in turn limits calcium shifting into the myocyte. Magnesium, a calcium antagonist, inhibits calcium channel pumps and competes with calcium binding to troponin. These additives help the impaired immature myocardium to maintain effective electrical and mechanical arrest. Hypertrophic ventricles, as seen in tetralogy of Fallot, may not be adequately protected with standard cardioplegia doses and may require a higher cardioplegia dose and longer delivery time to properly cool and perfuse the hypertrophied myocardium. Cyanotic patients with inadequate pulmonary blood flow often have increased bronchial collateral flow. High collateral flow to the lungs ultimately returns to the heart via the pulmonary veins and is undesired while the aorta is cross-clamped. Collateral flow can fill the heart, warm the myocardium, and wash out the cardioplegia from the myocardium. Lowering the systemic temperature not only helps to offset myocardial warming but also allows the perfusionist to lower the perfusion flow and pressure, which in turn reduces this collateral flow. Also, adequate LV venting helps to minimize the effect of volume returning to the heart. High sensitivity to the inflammatory response in the immature myocardium can cause edema and reduce ventricular compliance. Mannitol is an additive in del Nido cardioplegia and helps reduce intracellular water accumulation. Care must be taken to not perfuse the myocardium at too high a pressure. This could injure fragile coronary vessels and create myocardial edema. A pressure of 30–50 mm Hg has shown to be adequate.[82]

Inflammatory Response to CPB

The systemic inflammatory response syndrome (SIRS) instigated by CPB is well documented, and limiting this response is associated with improved outcomes.[83-85] Multiple factors including blood exposure to nonendothelialized surfaces (eg, CPB circuit, air); surgical trauma (eg, intubation, sternotomy); ischemia-reperfusion; hypothermia; and allogenic transfusion have been linked to this inflammatory activation. This complex response includes cascade activations of complement, cytokine, coagulation-fibrinolytic, and various cellular activations. Perioperative and postoperative consequences include multiple organ failure (eg, myocardium, renal, pulmonary, neurologic, hepatic), coagulopathy, edema, elaboration of injurious oxygen-free radicals, and hypotension.[85]

The SIRS is more pronounced in neonates; the degree of hemodilution, the need for longer CPB and ischemic times, and the more prevalent use of profound hypothermia are all known to exacerbate SIRS and are contributors to the increased postoperative morbidity seen in neonates compared with older infants and children.[86-88]

A number of contemporary pharmacologic strategies and CPB techniques are designed to attenuate the inflammatory reactions and remove mediators during CPB. Corticosteroids have been used during CPB for many years and have been shown to mitigate many inflammatory processes such as increased capillary permeability, edema, and leukocyte migration. Various timing and dosing protocols have been suggested with conflicting results.[89,90] At Children's Health Dallas a 30-mg/kg (1-g maximum dose) perioperative dose of methylprednisolone is administered to the CPB circuit prime. Additionally, 10 mg/kg of methylprednisolone is administered 8–12 hours before the initiation of CPB in neonates. Despite the large variability of preoperative and perioperative corticosteroid administration in clinical use, the literature generally demonstrates the benefit of CPB-induced systemic inflammatory response attenuation.[91-93]

Common CPB-based techniques to attenuate SIRS include ultrafiltration, circuit miniaturization, and the use of biocompatible circuit coatings. Ultrafiltration during CPB has been shown to reduce inflammatory mediators, pulmonary injury and edema, postoperative mechanical ventilation support time, and the perioperative need for blood transfusion.[94-97] CPB circuit miniaturization and the use of biocompatible surface coatings provide two main benefits in attenuating the inflammatory response. First, the smaller surface area of a miniaturized circuit and biocompatible coating reduces the bioreactivity of blood coming into contact with foreign surfaces.[32,33] Second, smaller circuits reduce overall hemodilution and the need to transfuse donor blood, both of which have been shown to exacerbate the inflammatory response.[55,56] Although the inflammatory response to CPB cannot be avoided, a multimodal approach can significantly reduce CPB-related SIRS.

Termination of CPB

Once the surgeon has completed the cardiac repair, the entry sites into the heart are sutured closed. The venous return drainage is retarded, which fills the right heart. The anesthesiologist inflates the lungs, which facilitates the movement of this blood across the pulmonary vasculature and back to the left heart. Any active left heart venting is paused at this point, and the surgeon massages the filling heart to expel

blood with any entrained air, out of a vent hole in the aortic root. Once there is no longer any air emanating from this site, the patient is placed into the Trendelenburg position and the cross clamp is removed from the aorta. The perfusionist then returns to full venous drainage, and the left heart vent can be placed to gentle suction again. The coronary circulation is now reperfused, washing out the cardioplegia. The heart is observed for any return of electrical activity. Temporary epicardial pacing wires are routinely placed, and pacing is initiated if the native rhythm does not promptly return. The left heart vent is removed before initiating ventilation to avoid entrainment air. Transesophageal echocardiography is then used to evaluate for the presence of air in the left heart as ventilation is restarted. If air is present, the vent site in the ascending aorta is kept open to evacuate it. Once the heart is confidently de-aired and the patient has returned to normothermia, the team agrees to wean from CPB. The perfusionist steadily reduces pump flow and venous return until the pump is fully off and the venous line is fully clamped. The patient's heart and lungs return to their native support roles at this point. Transesophageal, or in some cases epicardial, echocardiography is used to assess the adequacy of the repair. If the repair is deemed successful, a protamine dose, calculated by a heparin-protamine titration (discussed earlier in “Anticoagulation”), is administered. The cannulae are removed, and the purse strings are tied down. Adequate reversal of heparin is verified by measuring the ACT and heparin-protamine titration.

CHAPTER 38

Critical Care After Surgery for Congenital Cardiac Disease

V. Ben Sivarajan, Alexandre T. Rotta

PEARLS

- The neonatal myocardium is less compliant than that of the older child, is less tolerant of increases in afterload, and is less responsive to increases in preload.
- Echocardiography is the preferred imaging modality for the assessment and delineation of intracardiac anatomic features before surgery in children. Accurate anatomic diagnosis is now routine, so most children can have surgery without preoperative cardiac catheterization.
- A predictable decrease in cardiac index typically occurs 6 to 12 hours after separation from cardiopulmonary bypass.
- Milrinone administered during the early postoperative period plays a significant role in decreasing the likelihood of low cardiac output syndrome.
- Patients with postoperative low cardiac output require an extensive evaluation for unanticipated residual lesions, as this is more likely to be the case than the classical low cardiac output syndrome.
- Patients with restrictive physiology from hypertrophy and diastolic dysfunction of the right ventricle, such as those after tetralogy of Fallot repair, require high right-sided filling pressures to achieve adequate cardiac output. Consequently, these patients are more prone to hepatic congestion, anasarca, pleural effusions, and ascites.
- Inhaled nitric oxide plays an important role in the management of postoperative pulmonary hypertension in the cardiac intensive care unit. It is particularly effective in the postoperative course of patients with venous hypertensive disorders, such as total anomalous pulmonary venous connection, once mechanical obstruction is relieved.
- Hyperglycemia is a frequent occurrence in the cardiac intensive care unit and has been associated with increased morbidity and mortality during the postoperative period. However, tight glycemic control has not been shown to

improve outcomes in pediatric patients after cardiac surgery. In addition, the risks of significant hypoglycemia and its long-term attendant sequelae are greater in patients managed with a singular focus on tight glycemic control.
- Hypoxemia after bidirectional cavopulmonary anastomosis generally is a sign of decreased cardiac output, is poorly responsive to nitric oxide, and tends to improve with maneuvers that increase venous return through the superior vena cava, such as head elevation and controlled hypoventilation/mild hypercapnia.
- Liberation from positive pressure mechanical ventilation should be accomplished as soon as feasible in patients after a Fontan operation because spontaneous breathing improves pulmonary blood flow, arterial oxygen saturation, and ventricular preload.
- Ventricular ectopy and elevated atrial pressures after the arterial switch operation should raise suspicion of myocardial ischemia from insufficient coronary blood flow.
- Postoperative care of the patient with hypoplastic left heart syndrome after stage I palliation (Norwood procedure) requires adequate balancing of the pulmonary and systemic blood flows. A high arterial oxygen saturation denotes excessive pulmonary blood flow and is generally accompanied by decreased systemic blood flow, acidosis, and end-organ dysfunction.

Introduction

Congenital anomalies account for the largest diagnostic category among causes of infant mortality in the United States.[1] Structural heart disease leads the list of congenital malformations. Of the more than 4 million children born each year in the United States, nearly 40,000 have some form of congenital heart disease (CHD). Approximately half of these children appear for therapeutic intervention within the first year of life, and the majority of them require critical care expertise. Patients with congenital or acquired heart disease compose a major diagnostic category for admissions in large pediatric intensive care units (ICUs) across the country, representing 30% to 40% or more of ICU admissions in many centers.

Neonatal Considerations

Care of the critically ill neonate requires an appreciation of the special structural and functional features of immature organs, the interactions of the *transitional* neonatal circulation, and the secondary effects of the congenital heart lesion on other organ systems.[2-4] The neonate responds more quickly and profoundly to physiologically stressful circumstances, such as rapid changes in pH, lactic acid, blood glucose, and temperature. Neonates have diminished fat and carbohydrate reserves compared to older children. The higher metabolic rate and oxygen consumption of the neonate play a significant role in the rapid onset of hypoxemia when these patients become apneic. Immaturity of the liver and kidney may be associated with reduced protein synthesis and glomerular filtration such that drug metabolism is altered and hepatic synthetic function is reduced. These issues may be compounded by the normal increased total body water of the neonate compared with the older patient, along

with the propensity for capillary leakage. This is especially prominent in the lung of the neonate in whom the pulmonary vascular bed is nearly fully recruited at rest and lymphatic recruitment required to handle increased mean capillary pressures associated with increases in pulmonary blood flow may be unavailable.[4] The neonatal myocardium is less compliant than that of the older child, is less tolerant of increases in afterload, and is less responsive to increases in preload. Younger age also predisposes the myocardium to the adverse effects of cardiopulmonary bypass (CPB) and hypothermic ischemia implicit in support techniques used during cardiac surgery. These factors do not preclude intervention in the neonate but simply dictate that extraordinary vigilance be applied to the care of these children and that intensive care management plans account for the immature physiology.

The observed benefits of neonatal reparative operations in patients with two ventricles are numerous (Box 38.1). They continue to dictate that care of the newborn with complex CHD after CPB be a central feature of cardiac intensive care. Elimination of cyanosis and congestive heart failure (CHF) early in life optimizes conditions for normal growth and development. Palliative procedures such as pulmonary artery banding and creation of systemic-to-pulmonary artery shunts do not fully address cyanosis or CHF and may introduce their own set of physiologic and anatomic complications. Examples of improved outcomes with a single reparative operation rather than staged palliation as a newborn are well known and evoke little controversy. Approaches that have been abandoned include banding the pulmonary arteries in truncus arteriosus,[5] staging repair of type B interrupted aortic arch (IAA),[6] and staging repair of transposition of the great arteries with IAA.[7] In other conditions (eg, severely cyanotic newborn with tetralogy of Fallot [TOF]), the risks and benefits of neonatal repair versus a palliative shunt are debatable.[8]

Box 38.1

Advantage of Neonatal Repair

Early elimination of cyanosis

Early elimination of congestive heart failure

Optimal circulation for growth and development

Reduced anatomic distortion from palliative procedures

Reduced hospital admissions while awaiting repair

Reduced parental anxiety while awaiting repair

Whereas the neonate may be more labile than the older child, there is ample evidence that this age group is more resilient in its response to metabolic or ischemic injury. In fact, the neonate may be particularly capable of coping with some forms of stress. Tolerance of hypoxemia in the neonate is characteristic of many species,[9] and the plasticity of the neurologic system in the neonate is well known.[10] It is the rule rather than the exception that neonates presenting with shock secondary to obstructive left heart lesions can be effectively resuscitated without persistent organ

system impairment. The pliability and mobility of vascular structures in the neonate improve the technical aspects of surgery. Reparative operations in neonates take advantage of normal postnatal changes, allowing more normal growth and development in crucial areas such as myocardial muscle, pulmonary parenchyma, and coronary and pulmonary angiogenesis.

Postoperative pulmonary hypertensive events are more common in the infant who has been exposed to weeks or months of high pulmonary pressure and flow.[5] This is especially true for such lesions as truncus arteriosus, complete atrioventricular (AV) canal defects, and transposition of the great arteries (TGA) with ventricular septal defects (VSDs). Finally, cognitive and psychomotor abnormalities associated with months of hypoxemia or abnormal hemodynamics may be diminished or eliminated by early repair. However, if early reparative surgery results in more exposures to CPB (eg, repeated conduit changes) and associated adverse effects on cognitive or motor function, then the risk-to-benefit assessment must be modified accordingly.

Preoperative Care

Optimal preoperative care involves (1) initial stabilization, airway management, and establishment of adequate vascular access; (2) complete and thorough noninvasive delineation of the anatomic defect(s); (3) initiation/termination of prostaglandin therapy, as appropriate; (4) evaluation and treatment of secondary organ dysfunction, particularly the brain, kidneys, and liver; and (5) cardiac catheterization if necessary, typically for (a) physiologic assessment, (b) interventional procedures such as balloon atrial septostomy or valvotomy, or (c) anatomic definition not visible by echocardiography (eg, coronary artery distribution in pulmonary atresia with intact ventricular septum or delineation of aorticopulmonary collaterals in TOF with pulmonary atresia).

Physical Examination and Laboratory Data

Detailed history and physical examination are required, with focus on the extent of cardiopulmonary impairment, airway abnormalities, and associated extracardiac congenital anomalies.[11] Intrathoracic and extrathoracic airway problems in patients with Down syndrome, disorders of calcium homeostasis and immunologic deficiencies in patients with aortic arch abnormalities, and renal abnormalities in patients with esophageal atresia and CHD are a few of the associated conditions with which the anesthesiologist should be familiar. Intercurrent pulmonary infection is a common and significant finding in chronically overcirculated lungs. The presence, degree, and duration of hypoxemia are important details that, in the absence of iron deficiency, are reflected in the hematocrit. The nadir of physiologic anemia during infancy may contribute to left-to-right shunting by decreasing the relative pulmonary vascular resistance (PVR).[12]

Chest radiography can be used to assess heart size, pulmonary vascular congestion, airway compression, and areas of consolidation or atelectasis. The electrocardiogram (ECG) may reveal rhythm disturbances and demonstrate ventricular strain patterns (ST and T-wave changes) characteristic of unphysiologic pressure or volume burdens on the ventricles. Electrolyte abnormalities caused by CHF and forced diuresis also must be evaluated preoperatively, as severe

hypochloremic metabolic alkalosis may occur in some patients. It is important to discontinue digoxin preoperatively and to avoid hyperventilation and administration of calcium to these patients during induction of anesthesia, as the alkalotic hypokalemic, hypercalcemic, hypotensive, dilated, digoxin-bound myocardium fibrillates with ease.

Echocardiographic and Doppler Assessment

Advances in echocardiographic imaging have had an enormous impact on the diagnosis of CHD.[13] Accurate anatomic diagnosis now is routine in children without the need for cardiac catheterization. Echocardiography is the preferred imaging modality for the assessment of intracardiac anatomic features in young children. However, one should be aware of the current limitations of echocardiographic and Doppler techniques so that alternative diagnoses can be considered when intraoperative or postoperative findings are inconsistent with the working echocardiographic diagnosis.

Echocardiography can reliably determine atrioventricular and ventricular arterial alignment and the presence and location of intracardiac and great artery level shunts. Color Doppler is useful for estimating pressure gradients across discrete narrowings, such as septal defects and valves. It can also reliably estimate right ventricular systolic pressure, provided sufficient tricuspid regurgitation is present. Echocardiography is unreliable for imaging distal pulmonary artery stenosis and assessing gradients across long segments, such as a narrowed right ventricular to pulmonary artery conduit. Grading of AV valve regurgitation may be subjective and nonquantitative. Accuracy of transthoracic echocardiography can be limited by inadequate imaging windows in obese patients, older children, and some postoperative patients. The use of transesophageal or epicardial echocardiography in these patients can be helpful. In addition, selective use of three-dimensional echocardiography may improve diagnostic capabilities, such as defining the mechanism of valve regurgitation or visualization of complex anatomic features. As good as echocardiographic diagnosis of anatomic defects and Doppler measurements of pressure gradients and valve function have become, the standard for assessment of physiology when other clinical information is ambiguous or contradictory remains cardiac catheterization.

Cardiac Catheterization

When echocardiographic analysis with Doppler measurements and color flow mapping is complete and unambiguous, cardiac catheterization generally is not required in the preoperative assessment. Catheterization typically is not performed before infant or neonatal operations for VSDs, complete AV canal defects, TOF, TGA, IAA, hypoplastic left heart syndrome (HLHS), or coarctation of the aorta. However, in older patients with complex anatomy, such as a single ventricle, physiologic data from catheterization may be essential. This technique allows description of the direction, magnitude, and approximate location of intracardiac shunts. Intracardiac and intravascular pressures are measured to determine the presence of obstructions and whether shunt orifices are restrictive or nonrestrictive. Pressure gradients across sites of obstruction must be considered in light of

simultaneous blood flow; a small pressure gradient measured at a time of low cardiac output is misleading.

Normal intracardiac pressure and saturation values in children are described in Chapter 32. In the normal heart, blood in the pulmonary artery (PA) represents complete mixing of the systemic venous return; thus sampling of PA blood yields the true mixed venous oxygen saturation. It is possible to have small step-ups in oxygen saturation sequentially from the superior vena cava (SVC) to the PA in the absence of significant left-to-right shunts due to sampling bias (streaming). In the child with CHD, the SVC gives the best indication of true mixed venous oxygen saturation; a 5% or greater step-up in saturation downstream suggests the presence of a left-to-right shunt.[14] It would occur at the level of the right atrium with an atrial septal defect (ASD), in the right ventricle with a VSD, and in the pulmonary artery with a patent ductus arteriosus (PDA). The magnitude of the left-to-right shunt can be calculated from the Fick equation. The frequently used term Qp/Qs (pulmonary-to-systemic blood flow ratio) can be derived simply from the measured oxygen saturation values.

The patient whose aortic blood is fully saturated can be safely assumed to have no significant intracardiac right-to-left shunting. However, when an intracardiac right-to-left shunt is present, aortic blood is hypoxemic. In this situation, blood samples should also be obtained from the pulmonary veins, left atrium, and left ventricle for oxygen saturation determination and ascertainment of the source of desaturated blood. Pulmonary venous desaturation implies a pulmonary source of venous admixture (eg, pneumonia, atelectasis, or other pulmonary disease). Intrapulmonary shunting may substantially alter the anesthetic plan and the postoperative ventilatory requirements of the patient.

In the presence of a left-to-right shunt and elevated PVR, pressure and saturation measurements often are repeated with the patient breathing 100% oxygen to assess both the reactivity of the pulmonary vascular bed and any contribution of ventilation-perfusion abnormalities to hypoxemia. If breathing 100% oxygen increases pulmonary blood flow and dramatically increases Qp/Qs (with a fall in PVR), potentially reversible processes such as hypoxic pulmonary vasoconstriction likely are contributing to the elevated PVR. The patient with a high, unresponsive PVR and a small left-to-right shunt despite a large shunt orifice may have extensive and irreversible obstructive pulmonary vascular disease. If so, surgical repair usually is contraindicated if the child is older than 1 year.[15]

During cardiac catheterization, anatomic abnormalities are identified angiographically. Special angled views provide specific information about the location and extent of congenital defects.[16] Ventricular function is assessed angiographically and physiologically (eg, by pressure measurements). The calculated size of a cardiac chamber may have important bearing on its ability to support the circulation of a child with a hypoplastic ventricle.

Magnetic Resonance Imaging and Angiography

Magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) have emerged as important diagnostic modalities in the evaluation of the cardiovascular system following the development of ECG-gated MRI. Image acquisition is synchronized to the patient's ECG to counter motion artifacts and to

acquire cine sequences that allow detailed imaging of cardiac structures and visualization of blood flow throughout the cardiac cycle. In addition to providing excellent anatomic and three-dimensional images, particularly of the pulmonary veins and thoracic aorta, it also is possible with MRA to qualitatively assess valve and ventricular function and to quantify flow, ventricular volume, mass, and ejection fraction.[17,18] Whereas ferromagnetic implants near the region of interest might produce artifact, sternal wires and vascular clips produce relatively minor disturbances; therefore MRI generally can be performed in patients who have undergone previous cardiac surgery. Contraindications include patients with pacemakers, recently placed endovascular or intracardiac implants, and aneurysm clips on vessels that will be exposed directly to the magnetic field.

Assessment of Patient Status and Predominant Pathophysiology

Congenital heart defects can be complex and difficult to categorize or conceptualize. Rather than trying to determine the management for each individual anatomic defect, a physiologic approach can be taken. The following questions should be asked:

1. How does the systemic venous return reach the systemic arterial circulation to maintain cardiac output?

2. What, if any, intracardiac mixing, shunting, or outflow obstruction exists?

3. Is the circulation in series or parallel?

4. Are the defects amenable to a two-ventricle or single-ventricle repair?

5. Is pulmonary blood flow increased or decreased?

6. Is there a volume load or pressure load on the ventricles?

Appropriate organization of preoperative data, patient preparation, and decisions about monitoring, anesthetic agents, and postoperative care are best accomplished by focusing on a few major pathophysiologic problems, beginning with whether the patient is cyanotic, is in CHF, or both. Most pathophysiologic mechanisms that are pertinent to optimal patient preparation and to the perioperative plan focus on one of the following major problems: severe hypoxemia, excessive pulmonary blood flow, CHF, obstruction of blood flow from the left heart, and poor ventricular function. Although some patients with congenital heart disease present with only one of these problems, many have multiple interrelated issues.

Severe Hypoxemia

In the first few days of life, many of the cyanotic forms of CHD present with severe hypoxemia (PaO_2 <50 mm Hg) in the absence of respiratory distress. Infusion of prostaglandin E_1 (PGE_1) in patients with decreased pulmonary blood flow maintains or reestablishes pulmonary flow through the ductus arteriosus. This may also

improve mixing of venous and arterial blood at the atrial level in patients with transposition of the great arteries.[19] Consequently, neonates rarely require surgery while they are severely hypoxemic. During preoperative stabilization with PGE_1, neurologic examination and blood chemistry analysis of renal, hepatic, and hematologic function are necessary to assess the effects of severe hypoxemia during or after birth on end-organ dysfunction.

PGE_1 dilates the ductus arteriosus of the neonate with life-threatening ductus-dependent cardiac lesions and improves the patient's condition before surgery. PGE_1 can reopen a functionally closed ductus arteriosus even several days after birth, or it can maintain patency of the ductus arteriosus for several months postnatally.[19,20] The common side effects of PGE_1 infusion—apnea, hypotension, fever, central nervous system (CNS) excitation—are easily managed in the neonate when normal therapeutic doses of the drug (0.01–0.05 mcg/kg/min) are used.[21] However, PGE_1 is a potent vasodilator, so intravascular volume frequently requires augmentation. Patients with intermittent apnea resulting from administration of PGE_1 may require mechanical ventilation preoperatively; although apnea can resolve with the concomitant administration of aminophylline or caffeine.[22] PGE_1 usually improves the arterial oxygenation of hypoxemic neonates who have poor pulmonary perfusion as a result of obstructed pulmonary flow (critical pulmonic stenosis or pulmonary atresia) by providing pulmonary blood flow from the aorta via the ductus arteriosus. The improved oxygenation reverses the lactic acidosis that often develops during episodes of severe hypoxia. PGE_1 administration usually markedly improves the condition of a severely hypoxemic neonate with restricted pulmonary blood flow over minutes to hours.[23]

Excessive Pulmonary Blood Flow

Excessive pulmonary blood flow is frequently the primary problem of patients with CHD. The intensivist must carefully evaluate the hemodynamic and respiratory impact of left-to-right shunts and the extent to which it contributes to the perioperative course in the ICU. Children with left-to-right shunts may have chronic low-grade pulmonary infection and congestion that cannot be eliminated despite optimal preoperative preparation. If so, surgery should not be postponed further. Respiratory syncytial viral infections are particularly prevalent in this population, but advances in intensive care have markedly improved outcomes with this and other viral pneumonias.[24]

Aside from the respiratory impairment caused by increased pulmonary blood flow, the left heart must dilate to accept pulmonary venous return that might be several times normal. If the body requires more systemic blood flow, the heart responds inefficiently. Most of the increment in cardiac output is recirculated to the lungs. Eventually, symptoms of CHF appear. In the most severe cases, the evaluation reveals a severely malnourished child who is tachypneic, tachycardic, and dusky in room air. The child may have intercostal and substernal retractions and skin that is cool to the touch. Capillary refill may be prolonged. Expiratory wheezes usually are audible. Medical management with inotropes, systemic vasodilators, and diuretics may improve the patient's condition, but the diuretics may induce profound hypochloremic alkalosis and potassium depletion that often persist after surgery.

Obstruction of Left Heart Outflow

Patients who require surgery to relieve obstruction to outflow from the left heart are among the most critically ill children for whom the intensivist must care. These lesions include interruption of the aortic arch, coarctation of the aorta, aortic stenosis (AS), and mitral stenosis or atresia as part of the HLHS spectrum. These neonates present with inadequate systemic perfusion and profound metabolic acidosis. The initial pH may be below 7 despite a low $PaCO_2$. Systemic blood flow is largely or completely dependent on blood flow into the aorta from the ductus arteriosus.

Ductal closure in these neonates causes dramatic worsening of the patient's condition. The patient suddenly becomes critically ill and survival requires PGE_1 infusion to allow blood flow into the aorta from the pulmonary artery.[23,25] PGE_1 infusion improves perfusion and metabolism in neonates with acidosis, metabolic derangements, and renal failure because of inadequate systemic perfusion, so surgery generally can be deferred until stability is achieved. Ventilatory and inotropic support and correction of metabolic acidosis, along with calcium, glucose, and electrolyte abnormalities, should occur preoperatively. This stabilization period also allows assessment of the magnitude of end-organ dysfunction caused by the preceding period of inadequate systemic perfusion. Adequacy of stabilization, rather than severity of illness at presentation, appears to influence postoperative outcome the most.[26]

Ventricular Dysfunction

Ideally, the intensivist should participate in the preoperative care of all patients who are expected to recover in the ICU after surgery. Understanding the extent of ventricular dysfunction preoperatively provides considerable insight into intraoperative and postoperative events. Although patients with large shunts may have complete mixing but only mild-to-moderate hypoxemia as a result of their excessive pulmonary blood flow, the price paid for near-normal arterial oxygen saturation is chronic ventricular dilation and dysfunction and pulmonary vascular obstructive disease. Consequently, reducing the shunt fraction or using a staged approach to single-ventricle repair may be indicated. Older patients with CHD and poor ventricular function as a result of chronic ventricular volume overload (aortic or mitral valve regurgitation or long-standing pulmonary-to-systemic arterial shunts) present a different challenge, mitigated to some extent by afterload reduction. However, in all of these circumstances in hearts with chronic volume overload, there is a propensity for ventricular fibrillation during sedation, anesthesia, or intubation of the airway.

Assessment should include an estimation of the patient's functional limitation as an indicator of myocardial performance and reserve, quantification of the degree of hypoxia and amount of pulmonary blood flow, and evaluation of PVR. For patients with increased Qp/Qs, systemic blood flow should be optimized without further augmenting pulmonary flow during induction of anesthesia in the ICU or in the operating room. However, during maintenance and emergence from anesthesia, retraction of the lung, positional changes, and abdominal distension may increase the hypoxemia and compromise the function of a dilated, poorly contractile ventricle. If this sequence occurs during surgery, the management must be altered to improve pulmonary blood flow.

Postoperative Care

Assessment

When the clinical course of patients after cardiac surgery deviates from the usual expectation of uncomplicated recovery, our first responsibility is to verify the accuracy of the preoperative diagnosis and the adequacy of surgical repair. For example, a young infant who is acidotic, hypotensive, and cyanotic after surgical repair of TOF may tempt us to ascribe these findings to the vagaries of ischemia/reperfusion injury of CPB or transient, postoperative stiffness of the right ventricle. However, the real culprit may be an additional VSD undetected preoperatively and therefore not closed, a residual VSD around the surgical patch, or residual right ventricle (RV) outflow obstruction. Getting the right postoperative assessment is imperative and treatment follows accordingly. Evaluation of the postoperative patient relies on examination, monitoring, interpretation of vital signs, and imaging. Only once the accuracy of the diagnosis and adequacy of the repair are established can a low cardiac output state be presumed and treatment optimized. Treating low cardiac output states and preventing cardiovascular collapse often are the central features of pediatric cardiac intensive care and are the focus of this chapter (Box 38.2). The details of the specific considerations for selected lesions are presented in their respective sections.

Box 38.2

Ten Intensive Care Strategies to Diagnose and Support Low Cardiac Output States

1. Know in detail the cardiac anatomy and its physiologic consequences.
2. Understand the specialized considerations of the newborn and implications of reparative rather than palliative surgery.
3. Diversify personnel to include experts in neonatal and adult congenital heart disease.
4. Monitor, measure, and image the heart to rule out residual disease as a cause of postoperative hemodynamic instability or low cardiac output.
5. Maintain aortic perfusion and improve the contractile state.
6. Optimize preload (including atrial shunting).
7. Reduce afterload.
8. Control heart rate, rhythm, and synchrony.
9. Optimize heart lung interactions.

. Provide mechanical support when needed.

Optimizing preload involves more than just giving volume to a hypotensive patient. There are numerous considerations to fluid balance involving types of isotonic fluid, ultrafiltration in the operating room, optimal hematocrit, and the use of diuretics or vasopressors. Fluid itself can be detrimental if excess extravascular water results in interstitial edema and end-organ dysfunction of vital organs such as the heart, lungs, and brain. Occasionally, permitting a right-to-left shunt at the atrial level can optimize preload to the left ventricle in some conditions (discussed later). Maintaining aortic perfusion after CPB and improving the contractile state of the heart with higher doses of catecholamines are reasonable goals, but they may have particularly deleterious consequences in the newborn myocardium after hypothermic CPB. The benefits of afterload reduction are well known but, if excessive, may result in hypotension, coronary insufficiency, and cardiovascular collapse. Pacing the heart can stabilize the rhythm and hemodynamics, but it also may contribute to dyssynchronous, inefficient cardiac contraction or induce other arrhythmias. Although lifesaving in many instances, mechanical support of the failing myocardium in the form of extracorporeal life support (ECLS) or ventricular assist devices has its own set of limitations and morbidities. Almost every treatment approach has its own set of adverse effects. Supporting cardiac output in the postoperative patient is a balance between the promise and poison of therapy.

The initial assessment following cardiac surgery begins with review of the operative findings. This includes details of the operative repair and CPB, particularly total CPB or myocardial ischemic (aortic cross-clamp) times; concerns about myocardial protection; recovery of myocardial contractility; typical postoperative systemic arterial and central venous pressures; findings from intraoperative transesophageal echocardiography, if performed; and vasoactive medication requirements. This information guides subsequent examination, which should focus on the quality of the repair or palliation plus clinical assessment of cardiac output (Box 38.3). In addition to a complete cardiovascular examination, a routine set of laboratory tests should be obtained, including a chest radiograph, 12- or 15-lead ECG, blood gas analysis, serum electrolytes and glucose, ionized calcium and lactate measurements, complete blood count, and coagulation profile.

Box 38.3

Signs of Heart Failure or Low Cardiac Output States

Signs

Cool extremities/poor perfusion

Oliguria and other end-organ failure

Tachycardia

Hypotension

Acidosis

Cardiomegaly

Pleural effusions

Monitor and Assess

Heart rate, blood pressure, intracardiac pressure

Extremity temperature, central temperature

Urine output

Mixed venous oxygen saturation

Arterial blood gas pH and lactate

Laboratory measures of end-organ function

Echocardiography

Monitoring

Monitoring central venous pressure is routine for many patients following cardiac surgery, except those who undergo the least complex procedures. For example, a central venous catheter is not routinely placed for patients undergoing thoracic procedures, such as repair of aortic coarctation, division of a vascular ring, PDA ligation, or in patients undergoing cardiotomy with a short period of mildly hypothermic CPB, such as an ASD repair. Intracardiac or transthoracic left atrial (LA) catheters are often used to monitor patients after complex reparative procedures. Pulmonary arterial (PA) catheters now are seldom used but may be particularly useful if the postoperative management anticipates a problem such as pulmonary hypertension, thereby allowing rapid detection of pressure changes and assessment of the response to interventions.

Left atrial catheters are especially helpful in the management of patients with ventricular dysfunction, coronary artery perfusion abnormalities, or mitral valve disease. The mean LA pressure typically is 1 to 2 mm Hg greater than mean right atrial (RA) pressure, which generally varies between 1 and 6 mm Hg in nonpostoperative pediatric patients undergoing cardiac catheterization. In postoperative patients, mean LA and RA pressures are often greater than 6 to 8 mm Hg. However, they generally should be less than 15 mm Hg. The compliance of the right atrium is greater than that of the left atrium except in the newborn, so pressure elevations in the right atrium of older patients with two ventricles typically are less pronounced.

Possible causes of abnormally elevated LA pressure are listed in Box 38.4. In addition to pressure data, intracardiac catheters in the right atrium (or a percutaneously placed central venous catheter), left atrium, and pulmonary artery can be used to monitor the oxygen saturation of systemic or pulmonary venous blood and indicate the presence or absence of atrioventricular synchrony.

Box 38.4

Common Causes of Elevated Left Atrial Pressure After Cardiopulmonary Bypass

1. Decreased ventricular systolic or diastolic function

2. Left atrioventricular valve disease

3. Large left-to-right intracardiac shunt

4. Chamber hypoplasia

5. Intravascular or ventricular volume overload

6. Cardiac tamponade

7. Arrhythmia

Table 38.1 lists the causes of abnormally high or low RA, LA, and PA oxygen saturations, which can be measured at the bedside in the ICU. Following reparative surgery, patients with no intracardiac shunts and adequate cardiac output may have a mild reduction in RA oxygen saturation to approximately 60%. Lower RA oxygen saturation does not necessarily indicate low cardiac output. If a patient has arterial desaturation (common mixing lessons, lung diseases, etc.), the arteriovenous oxygen saturation difference is normally <30%. Hence even a low RA saturation may be in keeping with appropriate oxygen delivery and extraction. Elevated RA oxygen saturation often is the result of left-to-right shunting at the atrial level (eg, from the left atrium, anomalous pulmonary vein, or left ventricular [LV]-to-RA shunt). Blood in the LA normally is fully saturated with oxygen (ie, approximately 100%). The two chief causes of reduced LA oxygen saturation are an atrial level right-to-left shunt and pulmonary venous desaturation from abnormal gas exchange.

TABLE 38.1

Causes of Abnormal Right Atrial, Left Atrial, or Pulmonary Artery Oxygen Saturation

Location	Elevated	Reduced
RA	Atrial level left-to-right shunt	↑ Vo_2 (eg, low CO, fever)
	Anomalous pulmonary venous return	↓ Sao_2 saturation with a normal A-V O_2 difference
	Left ventricular-to-right atrial shunt	Anemia
	↑ Dissolved O_2 content ↓ O_2 extraction	Catheter tip position (eg, near CS)
	Catheter tip position (eg, near renal veins)	
LA	Does not occur	Atrial level right-to-left shunt
		↓ Pvo_2 (eg, parenchymal lung disease)
PA	Significant left-to-right shunt	↑ O_2 extraction (eg, low CO, fever)
	Small left-to-right shunt with incomplete mixing of blood	Sao_2 saturation with a normal A-V O_2 difference
	Catheter tip position (eg, PA "wedge")	Anemia

A-V, arteriovenous; *CO*, cardiac output; *CS*, coronary sinus; *LA*, left atrium; *PA*, pulmonary artery; *Pvo_2*, pulmonary vein oxygen tension; *RA*, right atrium; *Sao_2*, arterial oxygen saturation; *Vo_2*, oxygen consumption.

In the absence of left-to-right shunts, PA oxygen saturation is the best

representation of the “true” mixed venous oxygen saturation because all sources of systemic venous blood should be thoroughly combined as they are ejected from the right ventricle. When elevated, this saturation is useful in identifying residual significant left-to-right shunts following repair of a VSD. The absolute value of the PA oxygen saturation is a predictor of significant postoperative residual shunt. In patients following TOF or VSD repair, PA oxygen saturation greater than 80% within 48 hours of surgery with a fractional inspired oxygen concentration (FIO_2) <0.5 is a sensitive indicator of significant left-to-right shunt (Qp/Qs >1.5) 1 year after surgery.[27] Determination of PA oxygen saturation also can be useful in patients with systemic-to-pulmonary artery collaterals because flow from these vessels into the pulmonary arteries can increase oxygen saturation.

Low Cardiac Output Syndrome

Although low cardiac output after CPB is often attributable to residual or undiagnosed structural lesions, progressive low cardiac output states do occur. A number of factors have been implicated in the development of myocardial dysfunction following CPB including (1) the inflammatory response associated with CPB, (2) the effects of myocardial ischemia from aortic cross-clamping, (3) hypothermia, (4) reperfusion injury, (5) inadequate myocardial protection, and (6) ventriculotomy (when performed). The typical decrease in cardiac index has been well characterized in newborns following an arterial switch operation (ASO)[28] (Fig. 38.1). In a group of 122 newborns, the median maximal decrease in cardiac index that typically occurred 6 to 12 hours after separation from CPB was 32%.[28] One-fourth of these newborns reached a nadir of the cardiac index that was less than 2 L/min/m^2.[28] Anticipation of this low cardiac output syndrome (LCOS) and appropriate intervention can do much to avert morbidity or the need for mechanical support. Mixed venous oxygen saturation, whole blood pH, and lactate are laboratory measures commonly used to evaluate the adequacy of tissue perfusion and, hence, cardiac output.

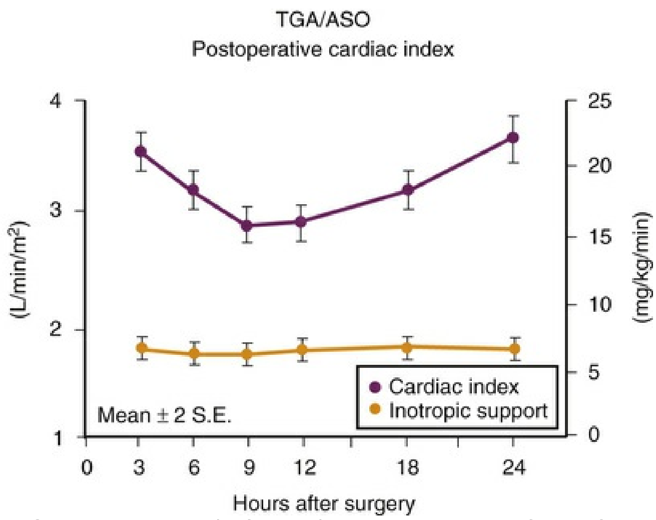

FIG. 38.1 Cardiac index (left axis) measured in infants following the arterial switch operation declined during the first 12 hours and was not the result of any reduction in inotropic support (right axis). One fourth of the

patients reach a value less than 2 L/min/m^2. The median reduction in cardiac index the first night is 33%. (From Wernovsky G, et al. Postoperative course and hemodynamic profile after the arterial switch operation in neonates and infants: a comparison of low-flow cardiopulmonary bypass and circulatory arrest. Circulation. 1995;92:2226-2235.)

Volume Adjustments

After CPB, the factors that influence cardiac output, such as preload, afterload, myocardial contractility, heart rate, and rhythm, must be continuously assessed and manipulated as needed. Volume therapy (increased preload) is commonly necessary, followed by appropriate use of inotropic and afterload-reducing agents. Atrial pressure and the ventricular response to changes in atrial pressure must be evaluated. Ventricular response is judged by observing systemic arterial pressure and waveform, heart rate, skin color, peripheral extremity temperature, peripheral pulse magnitude, urine flow, core body temperature, and acid-base balance.

Preserving and Creating Right-to-Left Shunts

Selected children with low cardiac output may benefit from strategies that allow right-to-left shunting at the atrial level in the face of expected postoperative RV dysfunction. A typical example is early repair of TOF, when the hypertrophied and poorly compliant right ventricle may be further compromised by increased volume load from pulmonary regurgitation secondary to a transannular patch on the RV outflow tract. These children will benefit from leaving the foramen ovale patent to permit right-to-left shunting of blood, thus preserving cardiac output and oxygen delivery despite the attendant transient cyanosis. If the foramen ovale is not patent or is surgically closed, RV dysfunction can lead to reduced LV filling, low cardiac output, and ultimately LV dysfunction. In infants and neonates with repaired truncus arteriosus, the same concerns apply and may even be exaggerated if RV afterload is elevated because of pulmonary hypertension.

Other Strategies

Additional strategies to support low cardiac output associated with cardiac surgery in children include use of atrio-biventricular pacing for patients with complete heart block or prolonged interventricular conduction delays and asynchronous contraction.[29] Appreciation of the hemodynamic effects of positive and negative pressure ventilation may be used to assist cardiac output. Avoidance of hyperthermia and even induced hypothermia may provide end-organ protection during periods of low cardiac output and aid in the management of postoperative arrhythmias, such as junctional ectopic tachycardia. Antiinflammatory agents including monoclonal antibodies, competitive receptor blockers, inhibitors of compliment activation, and preoperative preparation with steroids are being actively investigated in an effort to protect major organs from ischemic injury imposed by CPB and the reperfusion injury associated with the recovery period.

Right Ventriculotomy and Restrictive Physiology

Right ventricular *restrictive* physiology has been demonstrated by echocardiography as persistent antegrade diastolic blood flow into the pulmonary circulation following

reconstruction of the RV outflow in infants and children. This occurs in the setting of elevated RV end-diastolic pressure and RV hypertrophy, when the right ventricle demonstrates diastolic dysfunction with an inability to relax and fill during diastole. The poorly compliant RV usually is not dilated in this circumstance, and pulmonary valve regurgitation is limited because of the elevated RV diastolic pressure.[30,31]

The term *restrictive RV physiology* is also commonly used in the immediate postoperative period in patients who have a stiff, poorly compliant, and sometimes hypertrophied right ventricle. The elevated ventricular end-diastolic pressure restricts filling during diastole, causing an increase in right atrial filling pressure and, ultimately, systemic venous hypertension. Because of the phenomenon of ventricular interdependence, changes in RV diastolic function and septal position in turn affect LV compliance and function. Factors contributing to diastolic dysfunction include lung and myocardial edema following CPB, inadequate myocardial protection of the hypertrophied ventricle during aortic cross-clamp, coronary artery injury, residual outflow tract obstruction, volume load on the ventricle from a residual VSD or pulmonary regurgitation, and dysrhythmias. In many centers, a residual atrial communication is left to mitigate the perioperative sequelae associated with restrictive RV physiology, namely a low cardiac output state. In such a scenario, patients may be desaturated following surgery (typically 75% to 85% range) because of this right-to-left shunting, but they maintain systemic cardiac output while avoiding significant systemic venous hypertension. As RV compliance and function improve (usually within 2 to 3 postoperative days), the amount of shunt decreases and both antegrade pulmonary blood flow and SaO_2 increase.

If significant restrictive RV physiology develops in the absence of an unrestrictive atrial communication, a low cardiac output state with increased right-sided filling pressure (usually >10 mm Hg) ensues. Such patients often have cool extremities, are oliguric, and may have a metabolic acidosis. As a result of the elevated right atrial pressure, hepatic congestion, ascites, increased chest tube output, and pleural effusions may be evident. These patients may be tachycardic and hypotensive with a narrow pulse pressure. Preload must be maintained despite an already elevated RA pressure. Significant inotropic support often is required (typically dopamine 5 to 10 μg/kg/min or epinephrine 0.05–0.1 μg/kg/min). A phosphodiesterase inhibitor, such as milrinone, is potentially beneficial because of its lusitropic properties; however, one must be cautious in the use of these agents with renal impairment.[32] Sedation and paralysis often are necessary for the first 24 to 48 hours to minimize energy expenditure and associated myocardial work. Factors that further impair ventricular diastolic filling, such as loss of AV synchrony, accumulation of pleural fluid or ascites, and high tidal volume ventilation with air trapping, should be mitigated early in the postoperative course.

Mechanical ventilation may have a significant impact on RV afterload and the amount of pulmonary regurgitation. In addition, an increase in PVR because of hypothermia, acidosis, and either hypoinflation or hyperinflation of the lung also increases afterload on the right ventricle and pulmonary regurgitation. Synchronized intermittent positive pressure ventilation with the lowest possible mean airway pressure should be the aim, as discussed previously. This concept has been extended to older patients with single-ventricle physiology. The Fontan circulation relies on passive flow of blood through the pulmonary circulation without benefit of a pulmonary ventricle. If a fenestration is left at the time of the Fontan procedure, the

resulting right-to-left shunt helps to preserve cardiac output and results in fewer postoperative complications.[33,34] It is better to shunt blood right to left and accept some reduction in oxygen saturation (thus maintaining ventricular filling and cardiac output) than to have high oxygen saturation with a low cardiac output state.

Diastolic Dysfunction

Occasionally there is an alteration of ventricular relaxation, an active energy-dependent process, which reduces ventricular compliance. This is particularly problematic in patients with a hypertrophied ventricle undergoing surgical repair, such as TOF or Fontan surgery, and following CPB in some neonates when myocardial edema may significantly restrict diastolic function (ie, *restrictive physiology*).[30,31] The poorly compliant ventricle with impaired diastolic relaxation has a reduced end-diastolic volume and decreased stroke volume. β-Adrenergic antagonists and calcium channel blockers add little to the treatment of this condition. In fact, hypotension or myocardial depression produced by these agents often outweighs any gain from slowing the heart rate. Calcium channel blockers are relatively contraindicated in neonates and small infants because of their dependence on transsarcolemmal flux of calcium to both initiate and sustain contraction.

A gradual increase in intravascular volume to augment ventricular capacity, in addition to the use of low doses of inotropic agents, has proved to be of modest benefit in patients with diastolic dysfunction. Tachycardia must be avoided and AV synchrony maintained to optimize diastolic filling time and decrease myocardial oxygen demands. If low cardiac output continues despite treatment, therapy with vasodilators can be carefully attempted to alter systolic wall tension (afterload) and thus decrease the impediment to ventricular ejection. Because the capacity of the vascular bed increases after vasodilation, simultaneous volume replacement is often necessary. A noncatecholamine inodilator with vasodilating and lusitropic (improved diastolic state) properties, such as milrinone, is useful under these circumstances, in contrast with other inotropic agents.[35]

Pharmacologic Support

General principles of pharmacologic support in the neonatal and pediatric patient center on the recognition of the developmental limitations of the neonatal myocardium and the well-described reductions in cardiac output 6 to 12 hours after separation from CPB.[28] Despite ongoing development and maturity of adrenergic receptors and L-type calcium channels, catecholamine-based inotropic agents and vasodilators are efficacious in this population. These drugs have principles of use and side effects related to higher doses and patient-specific comorbidities. Other nonvasoactive agents serve as adjuncts to optimizing postoperative hemodynamics and fluid balance. The combination of a low-dose inotrope and an afterload reducing agent, or, more commonly, a phosphodiesterase inhibitor,[35] has been shown to decrease the occurrence of postoperative LCOS following CPB (Fig. 38.2).

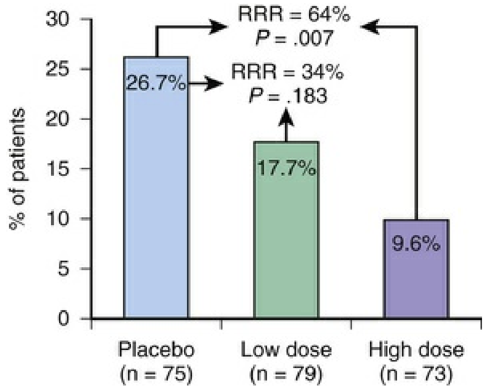

FIG. 38.2 Primary end point: development of low cardiac output syndrome (LCOS) or death in the first 36 hours. (From Hoffman, TM, et al. Efficacy and safety of milrinone in preventing low cardiac output syndrome in infants and children after corrective surgery for congenital heart disease. Circulation. 2003;107:996-1002.)

It should be understood that the need for vasoactive and inotropic support varies greatly among patients recovering from cardiac surgery and even over time for an individual patient progressing through the postoperative care continuum. The intensity of pharmacologic support employed must be constantly factored into the clinical assessment—the concept of intensity of therapy. One must not embrace a false sense of security when caring for a patient with adequate cardiac output when this requires disproportionate pharmacologic support. The current trend in cardiac critical care is to employ the lowest level of inotropic and vasoactive support necessary for adequate hemodynamic goals. Due to advances in preoperative stabilization, anesthetic strategies, surgical technique, myocardial protection, and CPB, it is not uncommon for a patient to return to the ICU requiring only modest doses of milrinone or epinephrine or no pharmacologic support at all. The specifics of cardiovascular pharmacology are discussed in Chapter 33.

Managing Acute Pulmonary Hypertension in the Intensive Care Unit

Children with many forms of CHD are prone to perioperative elevations in PVR.[36] This situation complicates the postoperative course, when transient myocardial dysfunction is further challenged by increased RV afterload.[37]

Although postoperative patients with pulmonary hypertension often are presumed to have active and reversible pulmonary vasoconstriction as the source of their pathophysiology, the intensivist is obligated to explore anatomic causes of mechanical obstruction that impose a barrier to pulmonary blood flow. Elevated LA pressure, pulmonary venous obstruction, branch pulmonary artery stenosis, or surgically induced loss of the vascular tree all raise RV pressure and impose an unnecessary burden on the right heart. Similarly, a residual or undiagnosed left-to-right shunt raises pulmonary artery pressure postoperatively and must be addressed surgically. Extended use of pulmonary vasodilator strategies only augments residual or undiagnosed shunts and increases the volume load on the heart.

Several factors peculiar to CPB may raise PVR: Pulmonary vascular endothelial dysfunction, microemboli, pulmonary leukostasis, excess thromboxane production, atelectasis, hypoxic pulmonary vasoconstriction, and adrenergic events all have been

suggested to play a role in postoperative pulmonary hypertension. Postoperative pulmonary vascular reactivity has been related not only to the presence of preoperative pulmonary hypertension and left-to-right shunts but also to the duration of total CPB. The threat of postoperative pulmonary hypertensive crises can be partially addressed by surgery at earlier ages, pharmacologic interventions, and other postoperative management strategies (Table 38.2).

TABLE 38.2

Critical Care Strategies for Postoperative Treatment of Pulmonary Hypertension

Encourage	Avoid
Anatomic investigation	Residual anatomic disease
Opportunities for right-to-left shunt as *pop-off*	Intact atrial septum in right heart failure
Sedation/anesthesia	Agitation/pain
Moderate hyperventilation	Respiratory acidosis
Moderate alkalosis	Metabolic acidosis
Adequate inspired oxygen	Alveolar hypoxia
Normal lung volumes	Atelectasis or overdistension
Optimal hematocrit	Excessive hematocrit
Inotropic support	Low output and coronary perfusion
Vasodilators	Vasoconstrictors/increased afterload

Pulmonary Vasodilators

Many intravenous vasodilators have been used with variable success in patients with pulmonary hypertensive disorders requiring critical care. Older-style vasodilators such as tolazoline, phenoxybenzamine, nitroprusside, or isoproterenol have little biologic basis for selectivity or enhanced activity in the pulmonary vascular bed.[38] However, if myocardial contractility is depressed and the afterload reducing effect on the left ventricle is beneficial to myocardial function and cardiac output, then these drugs may be of some value. In addition to drug-specific side effects, they all have potential to produce profound systemic hypotension, critically lowering coronary perfusion pressure while simultaneously increasing intrapulmonary shunt.

In the setting of pulmonary hypertension where the right ventricular contractile function is affected but LV contractility is intact, one can utilize a systemic vasopressor (in addition to inotropic agents and RV vasodilators) to optimize the circulation. The increase in end-arterial elastance results in increased LV contractility to maintain the ventricle on the same end-systolic PV curve. The increased afterload shifts the interventricular septum resulting in improved LV diastolic filling. The increased systolic contractility of the LV results in improved systolic contractility of the RV through shared fibers in the interventricular septum (systolic ventricular interdependence). Finally, the high afterload induced by the vasopressor results in better RV coronary perfusion pressure.

Even with selective infusions of rapidly metabolized, intravenously administered vasoactive drugs into the pulmonary circulation, systemic drug concentrations and systemic hemodynamic effects can be appreciable. Prostacyclin appears to have somewhat more selectivity for the pulmonary circulation but at high doses can precipitate a hypotensive crisis in unstable postoperative patients with refractory pulmonary hypertension. It is best suited for chronic outpatient therapy in severe forms of primary pulmonary hypertension.[39-41] Agents that improve ventricular

function in addition to reducing afterload (eg, type III phosphodiesterase inhibitors) are more appealing when cardiac output is low.

As an alternative approach to nonspecific vasodilators, it seems logical to target vasoconstrictors known to be associated with pathologic states or critical events. In this regard, endothelin, a potent vasoconstrictor, is elevated in persistent pulmonary hypertension of the newborn, in children with CHD, and in patients after CPB, and it seems a likely candidate for investigation of specific receptor blockers. Petrossian and colleagues[42] showed promising amelioration of postoperative pulmonary hypertension associated with CPB in animal models of increased pulmonary blood flow (from intracardiac shunts) when pretreated with endothelin-A receptor blockers. Undoubtedly, because the causes of pulmonary hypertension in the intensive care setting frequently are multifactorial, our "best" therapy will be multiply targeted. Adding phosphodiesterase V inhibitors to prostacyclin infusions, endothelin receptor blockers, thromboxane inhibitors, and inhaled nitric oxide (NO) all may have individual and combined merit with synergistic effects.

Nitric oxide is a selective pulmonary vasodilator formed by the endothelium from L-arginine and molecular oxygen in a reaction catalyzed by NO synthase. It then diffuses to the adjacent vascular smooth muscle cells where it induces vasodilation through a cyclic guanosine monophosphate-dependent pathway.[43,44] Because NO exists as a gas, it can be delivered by inhalation to the alveoli and then to the adjacent blood vessels. Once it diffuses across the wall of the pulmonary blood vessels, NO enters the vascular lumen where it is rapidly inactivated by hemoglobin, thus resulting in selective pulmonary vasodilation when pulmonary vasoconstriction exists. It has advantages over intravenously administered vasodilators that cause systemic hypotension and increase intrapulmonary shunting. Inhaled NO lowers pulmonary artery pressure in a number of diseases without the unwanted effect of systemic hypotension. This effect is especially dramatic in children with cardiovascular disorders and postoperative patients with pulmonary hypertensive crises.[37,45,46]

Therapeutic uses of inhaled NO in children with CHD abound in the ICU. For example, newborns with total anomalous pulmonary venous connection (TAPVC) frequently have obstruction of the pulmonary venous pathway as it connects anomalously to the systemic venous circulation. When pulmonary venous return is obstructed preoperatively, pulmonary hypertension is severe and demands urgent surgical relief. Increased neonatal pulmonary vasoreactivity, endothelial injury induced by CPB, and intrauterine anatomic changes in the pulmonary vascular bed in this disease contribute to postoperative pulmonary hypertension. In this postoperative setting, inhaled NO dramatically reduces pulmonary hypertension without adverse changes in heart rate, systemic blood pressure, or vascular resistance.

Patients with TAPVC, congenital mitral stenosis, and other pulmonary venous hypertensive disorders associated with low cardiac output are among the most responsive to NO. These infants are born with significantly increased amounts of smooth muscle in their pulmonary arterioles and veins. Histologic evidence of muscularized pulmonary veins and pulmonary arteries suggests the presence of vascular tone and capacity for change in resistance at both the arterial and venous sites. The increased responsiveness to NO seen in younger patients with pulmonary venous hypertension may result from pulmonary vasorelaxation at a combination of

precapillary and postcapillary vessels. Resolving the primary venous obstruction is of utmost importance before using NO in these lesions.

Several groups have reported successful use of inhaled NO in a variety of other congenital heart defects following cardiac surgery. NO is especially helpful when administered during a pulmonary hypertensive crisis.[47] Successful NO use has been described after the Fontan procedure, following late VSD repair, and with a variety of other anatomic lesions where patients are at risk of developing postoperative pulmonary hypertensive crises.[46-48] Oxygen saturation in response to inhaled NO generally does not improve in very young infants who are excessively cyanotic after a bidirectional Glenn anastomosis.[49] For these, increasing cardiac output and cerebral blood flow will have a much greater impact on arterial oxygenation, because elevated pulmonary vascular tone is seldom the limiting factor in the hypoxemic patient after the bidirectional Glenn operation.[50]

Inhaled NO can be used diagnostically in neonates with RV hypertension after cardiac surgery to discern those with reversible vasoconstriction. In patients with Ebstein's anomaly, a clinical response to NO can accurately differentiate between functional and anatomic pulmonary atresia.[51] In addition, the use of NO in such patients can facilitate anterograde pulmonary blood flow and hemodynamic stabilization. Failure of the postoperative newborn to respond to NO should be regarded as strong evidence of anatomic and possibly surgically remediable obstruction.[51]

If NO must be discontinued before the pathologic process has been resolved, hemodynamic instability can be expected. The withdrawal response to inhaled NO can be attenuated by pretreatment with the type V phosphodiesterase inhibitor sildenafil.[52] Sildenafil inhibits the inactivation of cyclic guanosine monophosphate within the vascular smooth muscle cell and has the potential to augment the effects of endogenous or exogenously administered NO to effect vascular smooth muscle relaxation. Sildenafil can be administered in an oral or IV form and has a somewhat selective pulmonary vasodilating capacity while lowering LA pressure and providing a modest degree of afterload reduction in some postoperative children. Chronic oral administration of sildenafil to adults with primary pulmonary hypertension improves exercise capacity. This phenomenon has also been demonstrated in pediatric patients with a Fontan circulation, perhaps suggesting a broad therapeutic application in both early and more remote postoperative congenital heart disease.

Cardiac Tamponade

Chest closure is a time of particular instability after operations for CHD. The infant's crowded mediastinum makes compression of the heart and cardiac tamponade an ever-present possibility after chest closure, despite patent drainage tubes and surgical resection of the anterior pericardium. The warning signs of tamponade frequently are subtle in small children, even minutes before cardiovascular collapse. Any significant deterioration in hemodynamics after chest closure should first be attributed to tamponade if ventilation and cardiac rhythm are adequate. The signs of tamponade include tachycardia, hypotension, narrow pulse pressure, and high filling pressures on both the left and right sides of the heart.

Acute myocardial perforation with tamponade occasionally occurs during

interventional cardiac catheterization procedures. Prompt support of the circulation with volume infusions and pressor support, along with immediate catheter drainage of the pericardial space, are essential in the event of this complication. Hemopericardium after ventricular puncture usually is self-limited, as the muscular ventricle seals the perforation after the responsible wire or catheter is removed. However, laceration of the thin-walled atrium may require suture repair under direct vision in the operating room.

Other causes of cardiac tamponade are seen in patients with CHD, and treatment frequently requires the assistance of an intensivist for either pericardiocentesis or sedation and monitoring for that definitive procedure. Postoperative tamponade from bleeding immediately after operation, as discussed earlier, is best handled by facilitation of chest tube drainage or reopening the sternotomy. Some children develop pericardial effusions during later phases of their illness because of hydrostatic influences (eg, patients with modified Fontan operations) or postpericardiotomy syndrome. Fluid in the pericardial space may accumulate under considerable pressure, and filling of the heart is impaired. If this problem is left unattended, the transmural pressure in the atria diminishes as intraatrial pressures rise, and diastolic collapse of the atria can be observed echocardiographically. Patients become symptomatic with a narrow pulse pressure, pulsus paradoxus, tachycardia, respiratory distress, decreased urine output, hyperkalemia, metabolic acidosis, and hypotension with tremendous endogenous catecholamine response.

In summary, aggressive identification and treatment of low cardiac output conditions after cardiac surgery are central to the critical care of children with CHD. Successful application of these strategies and thoughtful use of pharmacologic intervention undoubtedly have contributed to the remarkable decline in mortality associated with congenital heart surgery in the past two decades. However, despite these interventions, additional (mechanical) support is sometimes necessary as a bridge to recovery.

Diaphragmatic Dysfunction, Effusions, and Pulmonary Issues

Diaphragmatic paresis (reduced motion) or paralysis (paradoxical movement) may precipitate and promote respiratory failure, particularly in the neonate or young infant who relies on diaphragmatic function for breathing; older infants and children can recruit accessory and intercostal muscles if diaphragmatic function proves inadequate. Injury to the phrenic nerve, usually the left, may occur during operations that require dissection of the branch pulmonary arteries well out to the hilum (eg, TOF repair, ASO), arch reconstruction from the midline (eg, Norwood operation), manipulation of the SVC (Glenn shunt), takedown of a systemic-to-pulmonary shunt, or after attempted percutaneous central venous access. Phrenic nerve injury occurs more frequently at reoperation, when adhesions and scarring may obscure landmarks. Topical cooling with ice during deep hypothermia may also cause transient phrenic palsy. Increased work of breathing on low ventilator settings, increased $PaCO_2$, and a chest radiograph revealing an elevated hemidiaphragm suggest diaphragmatic dysfunction. The chest radiograph may be misleading, however, if it is obtained at the end of inspiration when lung volume is at its highest. Ultrasonography or fluoroscopy is useful for identifying diaphragmatic motion or

paradoxical excursion. Recovery of diaphragmatic contraction usually occurs; however, if a patient fails to tolerate repeated extubations despite optimizing cardiovascular and nutritional status and diaphragmatic dysfunction persists with volume loss in the affected lung, then surgical plication of the diaphragm may be required. Although only a temporary effect is gained, the prevention of collapse and volume loss in the affected lung often provides the critical advantage needed for liberation from positive pressure ventilation.

Pleural effusions and ascites may occur in patients after the Fontan operation or reparative procedures involving a right ventriculotomy (eg, TOF, truncus arteriosus) with transient RV dysfunction. Especially in young patients, pleural effusions and increased interstitial lung water may be a manifestation of right heart failure. This seems logically related to raised systemic venous pressure impeding lymphatic return to the venous circulation. The lymphatic circuit often is functioning at full capacity in these children. Pleural or peritoneal fluid and intestinal distension compete with intrapulmonary gas for thoracic space. Evacuation of the pleural space, drainage of ascites, and bowel decompression facilitate restoration of lung volume.

Pulmonary edema, pneumonia, and atelectasis are the most common causes of lower airway and alveolar abnormalities that interfere with gas exchange. If a bacterial pathogen is identified, antibiotics should be initiated promptly. If pulmonary edema is responsible for the gas exchange abnormality, therapy is aimed at lowering the LA pressure through diuresis and pharmacologic means to reduce afterload and improve the lusitropic state of the heart. For infants, fluid restriction frequently is incompatible with adequate nutrition; therefore an aggressive diuretic regimen is preferable to restriction of caloric intake. Adjustment of end-expiratory pressure and mechanical ventilation serve as supportive therapies until the alveoli and pulmonary interstitium are cleared of the fluid that interferes with gas exchange.

Separating From Mechanical Ventilation

Early tracheal extubation of children following congenital heart surgery is not a new concept but has received renewed attention with the evolution of fast-track management for cardiac surgical patients. Early extubation generally refers to tracheal extubation in the operating room or within a few hours (ie, 4-8 hours) after surgery, although in practice it means the avoidance of routine overnight mechanical ventilation. Factors to consider when planning early extubation are given in Table 38.3.

TABLE 38.3

Considerations for Planned Early Extubation After Congenital Heart Surgery

Patient factors	Limited cardiorespiratory reserve of the neonate and infant
	Pathophysiology of specific congenital heart defects
	Timing of surgery and preoperative management
Anesthetic factors	Premedication
	Hemodynamic stability and reserve
	Drug distribution and maintenance of anesthesia on bypass
	Postoperative analgesia
Surgical factors	Extent and complexity of surgery
	Residual defects

	Risks for bleeding and protection of suture lines
Conduct of bypass	Degree of hypothermia
	Level of hemodilution
	Myocardial protection
	Modulation of the inflammatory response and reperfusion injury
Postoperative management	Myocardial function Cardiorespiratory interactions
	Neurologic recovery
	Analgesia management

A number of published reports have described successful tracheal extubation in neonates and older children following congenital heart surgery, either in the operating room or soon after in the cardiac ICU.[53] This has been possible without adversely affecting patient care and with a low incidence of reintubation or hemodynamic instability. Such a process can reduce complications, like ventilator-associated events, and does not obviate meticulous attention to postoperative analgesia and sedation. The judicious use of this practice has streamlined the care of children and highlights the advances in perioperative care of infants and older children after repair of congenital heart defects.[54]

Central Nervous System

The dramatic reduction in surgical mortality has been accompanied by a growing recognition of neurologic morbidity in some survivors. Central nervous system abnormalities may be a function of coexisting (preexisting) brain abnormalities or acquired events unrelated to surgical management (eg, embolism, brain infection, effects of chronic cyanosis), but CNS insults appear to occur most frequently during or immediately after surgery. In particular, support techniques used during neonatal and infant cardiac surgery (eg, CPB, profound hypothermia, circulatory arrest) have been implicated as important causes of brain injury.[55]

During hypothermic CPB, multiple perfusion variables may influence the risk of brain injury. These variables include (but are not limited to) (1) the total duration of CPB, (2) the duration and rate of core cooling, (3) pH management during core cooling, (4) duration of circulatory arrest, (5) type of oxygenator, (6) presence of arterial filtration, (7) position and function of cannulae, and (8) depth of hypothermia. Undoubtedly, there is interaction between these various elements, and CNS injury following CPB most likely is multifactorial. Early postoperative studies (in the ICU) revealed a higher incidence of neurologic morbidity in patients undergoing circulatory arrest, including a higher incidence of clinical and electroencephalographic (EEG) seizures, a longer recovery time to the first reappearance of EEG activity, and greater release of the brain isoenzyme of creatine kinase.[55]

Seizures are the most commonly observed neurologic complication of cardiac surgery with an incidence in older studies of 4% to 25%. Although the incidence of seizures in the cardiac ICU has dramatically declined, when seizures do occur they should be treated aggressively. In addition, the broad availability of continuous EEG monitoring has allowed timely detection of treatment of previously undetectable but relevant subclinical seizures. Importantly, one must limit practices that may have been associated with brain injury after CPB: rapid cooling on CPB and use of prolonged hypothermic circulatory arrest, extreme alpha-stat strategy of intraoperative pH management, extreme hemodilution to hematocrits less than 20,

overheating infants upon arrival in the ICU, hypocapnic hyperventilation, and prolonged muscle relaxation (masking seizure observations). Elevated body temperature during critical illness is detrimental in the neurologic recovery of the critically ill and potentially brain-injured pediatric patient.

Intraventricular hemorrhage may occur as a consequence of perinatal events or circulatory collapse in the first few days of life and is commonly associated with prematurity. Although some centers routinely perform a head ultrasound on all newborns prior to cardiac surgery, data support limiting preoperative cranial ultrasound screening to those with existing risk factors.[56] Surgical intervention is delayed for several days if intraventricular bleeding is documented. The strategy of deferring operations in very premature newborns for several days after birth is associated with a low incidence of intraventricular hemorrhage in these high-risk patients despite use of CPB.[57]

Renal Function and Postoperative Fluid Management

Risk factors for postoperative renal failure include preoperative renal dysfunction, prolonged bypass time, low cardiac output, and cardiac arrest. In addition to relative ischemia and nonpulsatile blood flow on CPB, angiotensin II–mediated renal vasoconstriction and delayed healing of renal tubular epithelium have been proposed as mechanisms for renal failure. Postoperative sepsis and nephrotoxic drugs may further contribute to injury.

Because of the inflammatory response to bypass and significant increase in total body water, judicious fluid management in the immediate postoperative period is critical. Capillary leak and interstitial fluid accumulation may continue for the first 24 to 48 hours following surgery, necessitating ongoing intravascular volume replacement with colloid or blood products. A fall in cardiac output and increased antidiuretic hormone secretion contribute to delayed water clearance and potential prerenal dysfunction, which could progress to acute tubular necrosis and renal failure if a low cardiac output state persists.

During CPB, optimizing the circuit prime, hematocrit, and oncotic pressure; attenuating the inflammatory response with steroids; and use of modified ultrafiltration techniques have been recommended to limit interstitial fluid accumulation.[58] During the first 24 hours following surgery, maintenance fluids should be restricted to 50% to 66% of full maintenance and volume replacement titrated to appropriate filling pressures and hemodynamic response. Oliguria in the first 24 hours after complex surgery and CPB is common in neonates and infants until cardiac output recovers and neurohumoral mechanisms abate. Although diuretics are commonly prescribed in the immediate postoperative period, the neurohumoral influence on urine output is powerful. Time after CPB and enhancement of cardiac output through volume and pharmacologic adjustments are the most important factors that will promote diuresis.

Peritoneal dialysis, hemodialysis, and continuous venovenous hemofiltration provide alternate renal support in patients with severe oliguria and acute kidney injury (AKI). Besides enabling water and solute clearance, maintenance fluids can be increased to ensure adequate nutrition. The indications for renal support vary but include pronounced uremia, life-threatening electrolyte imbalance such as severe hyperkalemia, ongoing metabolic acidosis, fluid restrictions limiting nutrition, and

increased mechanical ventilation requirements secondary to persistent pulmonary edema or ascites.

A peritoneal dialysis catheter can be placed at the completion of surgery or as a bedside procedure later in the ICU. Indications include the need for renal support or for reducing intraabdominal pressure from ascites that may compromise mechanical ventilation and splanchnic perfusion. Drainage may be voluminous in the immediate postoperative period as third space fluid losses continue, and replacement with albumin or fresh-frozen plasma may be necessary to treat hypovolemia and hypoproteinemia.

Gastrointestinal Issues

Adequate nutrition is exceedingly important following cardiac surgery in neonates and children. These critically ill patients often have decreased caloric intake and increased energy demand after surgery; the neonate, in particular, has limited metabolic and fat reserves. Total parenteral nutrition can provide adequate nutrition in the hypercatabolic phase of the early postoperative period and generally is started on the first postoperative day if the prospect of meaningful enteral nutrition is unlikely.

Gastritis, ulcer formation, and upper gastrointestinal bleeding and may occur following the stress of cardiac surgery in children and adults. There are limited reports of the efficacy of proton pump inhibitors, histamine H_2 receptor blockers, sucralfate, or oral antacids in pediatric cardiac patients, although their use is common in most ICUs. Hepatic failure may occur after cardiac surgery, particularly after the Fontan operation, and typically is characterized by elevated liver enzymes and coagulopathy.

Necrotizing enterocolitis, although typically a disease of premature infants, is seen with increased frequency in neonates with CHD. Risk factors include (1) left-sided obstructive lesions, (2) umbilical or femoral arterial catheterization/angiography, (3) hypoxemia, and (4) lesions with wide pulse pressures (eg, systemic-to-pulmonary shunts and severe aortic regurgitation) producing diastolic runoff in the mesenteric vessels. Frequently, multiple risk factors exist in the same patient, making a specific etiology difficult to establish. Treatment includes continuous nasogastric suction, parenteral nutrition, and broad-spectrum antibiotics. Bowel exploration or resection may be necessary in severe cases.

Infection

Low-grade (<38.5°C) fever during the immediate postoperative period is common and may be present for up to 3 to 4 days, even without a demonstrable infectious etiology. However, one ought not to simply disregard the occurrence of fever in the days following surgery as it might signal an infection, especially in the multi-instrumented patient. CPB activates complement and other inflammatory mediators but also can lead to derangements of the immune system that increase the likelihood of infection.

Sepsis and nosocomial infection after cardiac surgery contribute substantially to overall morbidity. Despite the increased use of broad antibiotic coverage with third-generation cephalosporins, these agents do not seem to be more effective in

decreasing postoperative infections. Meticulous catheter insertion and daily care routines, along with early removal of indwelling catheters in the postoperative patient, are important in reducing the incidence of sepsis.[59] Optimal head positioning, mouth care, sedation management, and consideration of an early-extubation strategy can reduce the rates of ventilator-associated events.

Mediastinitis occurs in up to 2% of patients undergoing cardiac surgery. Risk factors include delayed sternal closure, early reexploration for bleeding, or reoperation. Mediastinitis is characterized by persistent fever, purulent drainage from the sternotomy wound, instability of the sternum, and leukocytosis. Staphylococcus is the most common offending organism. Treatment usually involves debridement and irrigation with parenteral antibiotic therapy. Duration of therapy depends on the severity of the infection and is generally between 2 and 4 weeks.

Hyperglycemia

Hyperglycemia is a frequent occurrence in the pediatric cardiac intensive care unit.[60,61] As many as 97% and 78% of patients exhibit at least one blood glucose measurement above 125 mg/dl and 200 mg/dl, respectively, following surgical repair of congenital cardiac defects.[60,61] The duration of postoperative hyperglycemia in these patients has been strongly and independently associated with increased morbidity and mortality rates.[60,61]

Strict glycemic control with insulin administration has been shown to reduce morbidity and mortality rates significantly for adult patients admitted to a surgical intensive care unit.[62] The first glycemic control outcome trial conducted in children with a sample largely composed of postoperative cardiac patients showed decreased mortality, shorter ICU length of stay, and decreased markers of inflammation in patients treated with insulin to maintain fasting blood glucose levels.[63] Of significant concern in that trial, however, was the finding that 24.9% of children undergoing strict glycemic control had at least one episode of severe hypoglycemia (blood glucose <40 mg/dL [2.2 mmoL/L]).[63] The use of a more permissive glycemic range (90-140 mg/dL) has been postulated as an optimal target that would be associated with a lower incidence of hypoglycemia without incurring the negative effects of hyperglycemia, compared to an euglycemic range.[64] Subsequently, two large trials conducted in this population have decreased the enthusiasm for aggressive glucose control in the early postoperative period. The ChiP trial randomized 1369 pediatric patients in 13 centers to either conventional (blood glucose <216 mg/dL [12.0 mmoL/L]) or tight (glycemic control 72-126 mg/dL [4.0-7.0 mmoL/L); 60% of trial participants had undergone cardiac surgery.[65] The primary end point of number of days alive and free from mechanical ventilation was comparable between the treatment groups (23. 2 versus 23.6 days; mean difference [95% confidence interval] 0.36 [-0.42, 1.14]); no differences were noted in the cardiac subgroup.[65] The SPECS trial randomized 980 children in 2 centers after surgery with CPB to either tight-glycemic control (80-110 mg/dL [4.4-6.1 mmoL/L]) or standard care with no prespecified glucose target.[66] In this study, there was no difference in the primary outcome (rate of health care–associated infection) between the two study groups (8.9 versus 9.8 per 1000 patient-days, respectively; p = 0.67). With no clear benefit demonstrated with the use of a tight glycemic control strategy, there is now greater focus on the hypoglycemic complications associated with such practice. Both studies demonstrated a significantly increased risk of any (CHiP: 15.9% versus 3.7%; p <0.001, SPECS: 19% versus 9%, p <0.001) or severe hypoglycemia (CHiP: 7.3% versus 1.5%; p <0.001, SPECS: 3% versus 1%, p = 0.03) with tight glycemic control.[65,66]

Critical Care Management of Selected Specific Lesions

Single-Ventricle Anatomy and Physiology

For a variety of anatomic lesions, the pulmonary and systemic circulations are in parallel with complete mixing, with a single ventricle effectively supplying both systemic and pulmonary blood flow. The proportion of ventricular output to either

the pulmonary or systemic vascular bed is determined by the relative resistance to flow in the two circuits. The pulmonary arterial and aortic oxygen saturations are equal. Assuming equal mixing, normal cardiac output, and full pulmonary venous saturation, SaO_2 of 80% to 85%, with MVO_2 of 60% to 65%, indicates Qp/Qs ≈1 and hence a balance between systemic and pulmonary flow. Although "balanced," the single ventricle still must receive and eject twice the normal amount of blood: one part to the pulmonary circulation and one part to the systemic circulation. A Qp/Qs >1 implies a volume burden on the heart that may have a clinical impact depending on the degree, duration, and myocardial reserve. Though lesion-specific considerations are important in the various types of single-ventricle physiology, common management principles to balance flow and augment systemic perfusion do apply.

Preoperative Management

Changes in PVR have a significant impact on systemic perfusion and circulatory stability, especially preoperatively when the ductus arteriosus is widely patent. In preparation for surgery, it is important that systemic and pulmonary blood flow be as well balanced as possible to prevent excessive volume overload and ventricular dysfunction that reduces systemic and end-organ perfusion. For example, a newborn with HLHS who has an arterial oxygen saturation greater than 90%, a wide pulse pressure, oliguria, cool extremities, hepatomegaly, and metabolic acidosis has severely limited systemic blood flow. Even though ventricular output is increased, the blood flow that is inefficiently partitioned back to the lungs is unavailable to the other vital organs. Immediate interventions are necessary to prevent imminent circulatory collapse and end-organ injury. In this "overcirculated" state, PVR is falling as it should in the normal postnatal state, and the ductus arteriosus is maintained widely patent to mitigate outflow obstruction from the RV to the systemic circulation. Blood flow manipulation by mechanical ventilation and inotropic support may temporarily stabilize the patient; this should accelerate the timeline for surgical intervention.

Similarly, in a patient with pulmonary atresia and an intact ventricular septum, LV-dependent pulmonary circulation occurs. Ductal patency is necessary for pulmonary blood flow. As PVR falls, pulmonary blood flow will be excessive and eventually will steal from the systemic circulation. Preoperative management should focus on an assessment of the balance between pulmonary (Qp) and systemic flow (Qs). This is best achieved by thorough and continuous reevaluation of the clinical examination for cardiac output state and perfusion; close monitoring of the oxygen saturation; evaluation of chest radiograph for cardiac size and pulmonary congestion; review of laboratory data for alterations in gas exchange, acid-base status, and end-organ function; and echocardiographic imaging to assess ventricular function and AV valve competence. A central venous line positioned in the proximal SVC may be useful to monitor volume status and sample central venous oxygen saturation as a surrogate of cardiac output and oxygen delivery. Central venous lines are not necessary in all circumstances; they may have significant complications in small newborns and do not substitute for clinical examination.

Initial resuscitation involves maintaining patency of the ductus arteriosus with a PGE_1 infusion at a rate of 0.01 to 0.05 μg/kg/min. Intubation and mechanical

ventilation are not necessary in all patients. Patients usually are tachypneic, but provided the work of breathing is not excessive and systemic perfusion is maintained without a metabolic acidosis, spontaneous ventilation often is preferable to achieve an adequate systemic perfusion and balance of Qp and Qs. A mild metabolic acidosis and low bicarbonate level may be present but may not indicate poor perfusion and a lactic acidosis specifically. If the initial presentation involved circulatory collapse and end-organ dysfunction, then a period of days may be required to establish stability and allow return of vital organ function prior to surgery.

Patients may require intubation and mechanical ventilation because of apnea secondary to PGE_1, presence of a low cardiac output state, or for manipulation of gas exchange to assist balancing Qp/Qs. A SaO_2 greater than 90% indicates pulmonary overcirculation—that is, Qp/Qs >1. PVR can be increased with controlled mechanical hypoventilation to induce a respiratory acidosis, often necessitating sedation and neuromuscular blockade, and with a reduction of ambient FiO_2 to minimize hyperoxic pulmonary vasodilation. Ventilation in room air may suffice, but occasionally a hypoxic gas mixture is necessary. This is achieved by adding nitrogen to the inspired gas mixture, reducing the FiO_2 to around 0.17 to 0.19. Although these maneuvers often are successful in maintaining a relatively high PVR and reducing pulmonary blood flow, it is important to remember that these patients have a limited oxygen reserve and may desaturate suddenly and precipitously. Controlled hypoventilation reduces functional residual capacity (FRC) and therefore also decreases the oxygen reserve, which is further reduced by use of a hypoxic inspired gas mixture. An alternate strategy is to add carbon dioxide to the inspiratory limb of the breathing circuit, which also increases PVR, but because a hypoxic gas mixture is not used, systemic oxygen delivery is maintained.[67,68] Patients who have continued pulmonary overcirculation with high SaO_2 and reduced systemic perfusion despite these maneuvers require early surgical intervention to control pulmonary blood flow. At the time of surgery, a temporary snare can be placed around either branch of the pulmonary artery to effectively limit pulmonary blood flow. Alternatively, if there are important comorbidities that preclude a standard palliative operation (prematurity, intracranial hemorrhage), bilateral pulmonary arterial bands can be placed through a median sternotomy to effect optimization of systemic blood flow.

Decreased pulmonary blood flow in preoperative patients with a parallel circulation is reflected by hypoxemia with SaO_2 less than 75%. This may result from restricted flow across a small ductus arteriosus, increased PVR secondary to parenchymal lung disease, or increased pulmonary venous pressure secondary to obstructed pulmonary venous drainage or a restrictive ASD. In patients with a later postnatal presentation, blood flow through a restrictive ductus may be augmented by the administration of high-dose PGE_1 (0.1-0.2 μg/kg/min). Patients at this level of prostaglandin delivery should have their airway secured and may benefit from vasopressor therapy to both offset the vasodilating effects of PGE_1 and increase the systemic vascular resistance (SVR) to augment pulmonary blood flow. Sedation, paralysis, and optimization of mechanical ventilation to maintain an alkalosis may be effective if PVR is elevated. NO may be also be useful in selected cases. Systemic oxygen delivery is maintained by improving cardiac output and maintaining hematocrit >40%. Among some newborns with HLHS, pulmonary blood flow may

be insufficient because mitral valve hypoplasia in combination with a restrictive or nearly intact atrial septum severely restricts pulmonary venous return to the heart. The newborn is intensely cyanotic and has a pulmonary venous congestion pattern on chest radiograph. Urgent interventional cardiac catheterization with balloon septostomy or dilation (or stent placement) of a restrictive ASD may be necessary.[69,70] Immediate surgical intervention and palliation are preferred in some centers. Increasingly, these patients are being identified prenatally with an option of fetal catheter-based intervention. Despite such advances, survival in this subgroup is reduced (between 48% and 69%).[70-74]

Systemic perfusion is maintained with the use of volume and vasopressor agents. Inotropic support often is necessary because of ventricular dysfunction secondary to the increased volume load. Systemic afterload reduction with agents such as phosphodiesterase inhibitors may improve systemic perfusion, although they also may decrease PVR and thus not correct the imbalance of pulmonary and systemic flow. Oliguria and a rising serum creatinine level may reflect renal insufficiency from a low cardiac output. Necrotizing enterocolitis is a risk secondary to splanchnic hypoperfusion, and we prefer not to enterally feed newborns with a wide pulse width and low diastolic pressure (usually <30 mm Hg) prior to surgery. It is important to continuously evaluate end-organ perfusion and function.

Postoperative Management

The postoperative management of patients with single ventricle anatomy and physiology will be discussed later in this chapter, in the section detailing postoperative care of newborns with HLHS following stage I palliation.

Bidirectional Cavopulmonary Anastomosis

In this procedure, also known as a bidirectional Glenn (BDG) shunt, the SVC is transected and connected end-to-side to the right pulmonary artery, while the pulmonary arteries remain in continuity. Therefore flow from the SVC is bidirectional into both left and right pulmonary arteries. The SVC becomes the only source of pulmonary blood flow, and IVC blood returns to the common atrium. Performed between age 3 to 6 months, the BDG has proved to be an important early staging procedure in single-ventricle physiology for relieving volume and pressure overload, pulmonary artery distortion, and coronary hypoperfusion associated with an aortopulmonary shunt. However, BDG circulation is not a stable source of pulmonary blood flow in the first few months of life when pulmonary cross-sectional area is inadequate to accommodate sufficient passive pulmonary blood flow for tolerable oxygenation. The BDG usually is performed on CPB using mild hypothermia with a beating heart. Therefore the complications related to CPB and aortic cross-clamping are minimal, and patients can be weaned and extubated in the early postoperative period.[75] In selected cases, the BDG anastomosis can be accomplished without CPB.

Systemic hypertension is common following a BDG. The etiology remains to be determined, but possible factors include improved contractility and stroke volume after the volume load on the ventricle is reduced, and brain stem–mediated mechanisms secondary to the increased systemic and cerebral venous pressure. Treatment with vasodilators may be necessary during the early postoperative

period.

Following the BDG anastomosis, arterial oxygen saturation should be in the 80% to 85% range; however, stabilization to this level can take a number of days. In addition, positive pressure ventilation in these patients reduces passive pulmonary blood, so oxygen saturation frequently improves after extubation. Persistent hypoxemia (SaO_2 <70%) can be secondary to a low cardiac output state (low SvO_2), low pulmonary blood flow, or lung disease (Table 38.4). Treatment is directed at improving contractility, reducing afterload, and ensuring the patient has a normal rhythm and hematocrit. Increased PVR is an uncommon cause, and inhaled NO is rarely beneficial in these patients.[49] This finding is not surprising because PA pressure and resistance and vascular tone are not high enough following this surgery to see a demonstrable benefit from NO. Persistent profound hypoxemia should be investigated in the catheterization laboratory to evaluate hemodynamics, look for residual anatomic defects limiting pulmonary flow, such as SVC or PA stenosis or a restrictive ASD, and coil any significant venous decompressing collaterals (eg, azygous vein), if present.

TABLE 38.4

Factors Contributing to a Lower Than Anticipated Oxygen Saturation in Patients With Common Mixing Lesions

Etiology	Considerations
Low FIO_2	Low delivered oxygen concentration
	Failure of oxygen delivery device
Pulmonary vein desaturation	1. Ventilation-perfusion defects
	Alveolar process (eg, edema/infection/atelectasis)
	Restrictive process (eg, effusion/bronchospasm)
	2. Intrapulmonary shunt
	Severe RDS
	Pulmonary AVM
	PA-to-PV collateral vessel(s)
↓ Pulmonary blood flow	Anatomic RV outflow obstruction
	Anatomic pulmonary artery stenosis
	Increased PVR
	Atrial level right-to-left shunt
	Ventricular level right-to-left shunt
↓ Oxygen content	1. Low mixed venous oxygen level
	Increased O_2 extraction: Hypermetabolic state
	Decreased O_2 delivery: Low cardiac output state
	2. Anemia

AVM, arteriovenous malformation; *FIO_2*, fractional inspired concentration of oxygen; *PA*, pulmonary artery; *PV*, pulmonary vein; *PVR*, pulmonary vascular resistance; *RDS*, respiratory distress syndrome; *RV*, right ventricle.

Fontan Procedure

Since the original description in 1971,[76] the Fontan procedure and its subsequent modifications have been successfully used to treat a wide range of single-ventricle congenital heart defects.[77] The surgical reconstruction is "physiologic" in that the systemic and pulmonary circulations are in series and cyanosis is corrected. However, given the current long-term outcome data, its is important to remember that the operation is still palliative rather than curative.[78,79] The mortality and morbidity associated with this surgery have declined substantially over the years,

and many patients with stable single-ventricle physiology can lead reasonably normal lives.[80]

Considerations in managing a cavopulmonary connection are given in Table 38.5. Systemic venous pressure of 10 to 15 mm Hg and LA pressure of 5 to 10 mm Hg—that is, a transpulmonary gradient of 5 to 10 mm Hg—is ideal. Intravascular volume must be maintained and hypovolemia must be treated promptly. Venous capacitance is increased, and as patients rewarm and vasodilate following surgery, a significant volume requirement of approximately 30 to 40 ml/kg on the first postoperative night is not unusual.

TABLE 38.5

Management Considerations Following a Modified Fontan Procedure

	Aim	Management
Baffle (right side)		→ or ↑ Preload
Pressure 10-15 mm Hg	Unobstructed venous return	Low intrathoracic pressure
	PVR <2 Wood units m^2	Avoid increases in PVR, such as from acidosis, hypoinflation and hyperinflation of the lung, hypothermia, and excess sympathetic stimulation
Pulmonary circulation	Mean Pap <15 mm Hg	Early resumption of spontaneous respiration
	Unobstructed pulmonary vessels	
Left atrial	Sinus rhythm	Maintain sinus rhythm
Pressure 5-10 mm Hg	Competent AV valve	→ or ↑ Rate to increase CO
	Ventricle	→ or ↓ Afterload
	Normal diastolic function	→ or ↑ Contractility
	Normal systolic function	PDE inhibitors useful because of vasodilatory, inotropic, and lusitropic properties
	No outflow obstruction	

AV, atrioventricular; *CO*, cardiac output; *Pap*, pulmonary arterial pressure; *PDE*, phosphodiesterase; *PVR*, pulmonary vascular resistance.

Changes in mean intrathoracic pressure and PVR have a significant effect on pulmonary blood flow. Pulmonary blood flow has been shown to be biphasic following the Fontan procedure, and earlier resumption of spontaneous ventilation is recommended to offset the detrimental effects of positive pressure ventilation.[81,82] Using Doppler analysis, it has been demonstrated that pulmonary blood flow predominantly occurs during inspiration in a spontaneously breathing patient—that is, when the mean intrathoracic pressure is subatmospheric. Therefore the method of mechanical ventilation following a Fontan procedure requires close observation. A tidal volume of 8 to 10 ml/kg with the lowest possible mean airway pressure is optimal. If appropriate selection criteria are followed, patients undergoing a modified Fontan procedure will have a low PVR without labile pulmonary vascular resistance. Vigorous hyperventilation and induction of a respiratory or metabolic alkalosis are often of little benefit in this group of patients, and the related increase in mechanical ventilation requirements may lead to injury. A normal pH and $PaCO_2$ of 40 mm Hg should be the goal and, depending on the amount of right-to-left shunt across the fenestration, the arterial oxygen saturation usually is in the 80% to 90% range. However, PVR may increase following surgery, particularly secondary to an acidosis, hypothermia, atelectasis and hypoventilation, vasoactive drug infusions,

and stress response. Any acidosis must be treated promptly. If the cause is respiratory, ventilation must be adjusted. A metabolic acidosis reflects poor cardiac output and treatment directed at the potential causes, including reduced preload to the systemic ventricle, poor contractility, increased afterload, and loss of sinus rhythm. The effects of transient increases in PVR can be mitigated by the standard use of a fenestration of the Fontan circuit. This functions similarly to a residual PFO after a TOF repair where systemic hypoxemia (SaO_2) from the right-to-left shunt is the price paid for maintenance of systemic cardiac output.

The use of PEEP requires thoughtful consideration based on patient-specific postoperative circumstances. The beneficial effects of a PEEP-related increase in FRC, maintenance of lung volume, and redistribution of lung water must be carefully balanced against the possible detrimental effect of an increase in mean intrathoracic pressure on passive pulmonary blood flow. A PEEP of 3 to 5 cm H_2O, however, rarely has either hemodynamic consequence or substantial effect on effective pulmonary blood flow.

Alternative methods of mechanical ventilation have been used in these patients. High-frequency ventilation has employed successfully in selected cases, although the potential hemodynamic consequences of the raised mean intrathoracic pressure must be continually evaluated. Airway pressure-release ventilation has been shown to be superior in preserving systemic cardiac output when compared with standard pressure/volume control ventilation in patients post-Fontan completion.[83] Negative pressure ventilation can be beneficial by augmenting pulmonary blood flow.[84] The development of new negative pressure ventilators, cuirasses, and jackets have increased the interest in this mode of ventilation for this group of patients, but the experience is relatively small and indications are not defined. Application is cumbersome in the patient with surgical site dressings and chest tubes typically present after a midline sternotomy. In many centers, patients after a standard risk Fontan completion are identified for early extubation (in the operating room or within 6 hours of ICU admission), thus mitigating some of the aforementioned concerns. With proper selection criteria, optimal CPB management, and early extubation, most patients have an uncomplicated course after Fontan completion and can be discharged from the ICU environment within 1 or 2 days.

Nonspecific pulmonary vasodilators, such as sodium nitroprusside, glycerol trinitrate, PGE_1, and prostacyclin, have been used to dilate the pulmonary vasculature in an effort to improve pulmonary blood flow after a Fontan procedure, but the results have been variable. Although PVR may fall, pulmonary blood flow also could increase as a result of reduced ventricular end-diastolic pressure following improved ventricular function secondary to the fall in systemic afterload. The response to inhaled NO also is variable, and the improvement may be related to changes in ventilation/perfusion matching rather than a direct fall in PVR.

Afterload stress is poorly tolerated after a modified Fontan procedure because of the increase in myocardial wall tension and end-diastolic pressure. A phosphodiesterase inhibitor like milrinone is particularly beneficial. Besides being a weak inotrope with pulmonary and systemic vasodilating properties, its lusitropic action assists by improving diastolic relaxation and lowering ventricular end-diastolic pressure, thereby improving effective pulmonary blood flow and cardiac output.

Complications After the Fontan Procedure

Pleuropericardial Effusions

The incidence of recurrent pleural effusions and ascites has decreased since the introduction of the fenestrated baffle technique. Nevertheless, for some patients they remain a major problem with associated respiratory compromise, hypovolemia, and possible hypoproteinemia. They usually occur secondary to persistent elevation of systemic venous pressure, and reevaluation with cardiac catheterization may be indicated.

Rhythm Disturbances

Junctional bradycardia after Fontan completion is commonly observed postoperatively and rarely affects cardiac output significantly; in the rare circumstance where that occurs, the use of AAI pacing rapidly addresses the situation. Atrial flutter or fibrillation, heart block, and, less commonly, ventricular dysrhythmia may have a significant impact on immediate recovery and on long-term outcome.[85] Sudden loss of sinus rhythm initially causes an increase in LA and ventricular end-diastolic pressure and a fall in cardiac output. The SVC or PA pressure must be increased, usually with volume replacement, to maintain the transpulmonary gradient. Prompt treatment with antiarrhythmic drugs, pacing, or cardioversion is necessary.

Premature Closure of the Fenestration

Not all patients require a fenestration for a successful, uncomplicated Fontan operation. Those with ideal preoperative hemodynamics often maintain adequate pulmonary blood flow and cardiac output without requiring a right-to-left shunt across the baffle. Similarly, not all Fontan patients who received a fenestration use it for a right-to-left shunt in the immediate postoperative period. These patients are fully saturated following surgery and may have an elevated right-sided filling pressure but nevertheless maintain an adequate cardiac output. The challenge is predicting which patients are at risk for low cardiac output after a Fontan procedure and who will benefit from placement of a fenestration. Even patients with ideal preoperative hemodynamics may manifest a significant low output state after surgery. In a review of 2747 Fontan completions from 68 centers contributing to the Society of Thoracic Surgeons (STS) database, 65% received a surgical fenestration at the time of initial operation.[86] Premature closure of the fenestration may occur in the immediate postoperative period, leading to a low cardiac output state with progressive metabolic acidosis and large chest drain losses from systemic venous hypertension. Patients may respond to volume replacement, inotrope support, and vasodilation; however, if hypotension and acidosis persist, cardiac catheterization and removal of thrombus or dilation of the fenestration may be urgently needed.

Persistent Hypoxemia

Arterial O_2 saturation levels may vary substantially following a modified Fontan procedure. Common causes of persistent arterial O_2 desaturation less than 75% include a poor cardiac output with a low SvO_2, a large right-to-left shunt across the fenestration, and additional "leak" in the baffle pathway producing more shunting.

Persistent hypoxemia can also be caused by an intrapulmonary shunt or venous admixture from decompressing vessels draining from the systemic venous baffle to the pulmonary venous system. Reevaluation with conventional or bubble contrast echocardiography and cardiac catheterization may be necessary.

Low Cardiac Output State

An elevated LA pressure after a modified Fontan procedure may reflect poor ventricular function from decreased contractility or increased afterload stress, atrioventricular valve regurgitation, or loss of sinus rhythm (Table 38.6). Treatment consists of maintaining the high right-sided filling pressures (to maintain the transpulmonary gradient) and initiating inotropes and vasodilators. If a severe low output state with acidosis persists, takedown of the Fontan operation and conversion to a BDG anastomosis or other palliative procedure might be lifesaving. Central venoarterial extracorporeal membrane oxygenation (VA ECMO) support in this instance may be an effective bridging strategy to urgent reoperation. Emergent cannulation to VA ECMO after BDG and Fontan is associated with high morbidity and mortality and is generally contraindicated.[87,88]

TABLE 38.6

Etiology and Treatment Strategies for Patients With Low Cardiac Output Immediately Following the Fontan Procedure

Low Cardiac Output	Etiology	Treatment
Increased TPG		
Baffle >20 mm Hg LAp <10 mm Hg ↑ TPG ≫10 mm Hg	Inadequate pulmonary blood flow and preload to left atrium Increased PVR Pulmonary artery stenosis	Volume replacement Reduce PVR Correct acidosis Inotropic support
Clinical State		
High SaO_2/low SvO_2 Hypotension/tachycardia Core temperature high Poor peripheral perfusion SVC syndrome with pleural effusions and increased chest tube drainage Ascites/hepatomegaly Metabolic acidosis	Pulmonary vein stenosis Premature fenestration closure	Systemic vasodilation Catheter or surgical intervention
Normal TPG		
Baffle >20 mm Hg LAp >15 mm Hg TPG normal 5-10 mm Hg	Ventricular failure Systolic dysfunction Diastolic dysfunction AVV regurgitation or stenosis	Maintain preload Inotrope support Systemic vasodilation Establish sinus rhythm or atrioventricular synchrony
Clinical State		
Low SaO_2/low SvO_2 Hypotension/tachycardia Poor peripheral perfusion Metabolic acidosis	Loss of sinus rhythm ↑ Afterload stress	Correct acidosis Mechanical support Surgical intervention, including takedown to BDG and transplantation

AVV, atrioventricular valve; *BDG*, bidirectional Glenn anastomosis; *LAp*, left atrial pressure; *PVR*, pulmonary vascular resistance; *Sao_2*, systemic arterial oxygen saturation; *SVC*, superior vena cava; *Svo_2*, SVC oxygen saturation; *TPG*, transpulmonary gradient.

Patent Ductus Arteriosus

Pathophysiology

The ductus arteriosus is a fetal vascular communication between the main pulmonary artery at its bifurcation and the descending aorta below the origin of the left subclavian artery. When patent, it provides a simple shunt between the systemic and pulmonary arteries. The magnitude and direction of flow between the systemic and pulmonary vessels are determined by the relative resistances to flow in the two vascular beds and the resistance of the ductus itself. With a large, nonrestrictive ductus and low PVR, the pulmonary blood flow is excessive and the volume load of the left heart is large. Systolic and diastolic flow away from the aorta may steal blood from vital organs and compromise end-organ function at many sites.[89] In addition, overcirculated lungs and elevated LA pressure increase the work of breathing.[90,91]

Critical Care Management

Although the PDA of premature infants can often be closed medically with indomethacin, contraindications to use of this agent (eg, intracranial hemorrhage, renal dysfunction, and hyperbilirubinemia) may require surgical closure of the defect.[92] Thoracotomy and surgical ligation of the ductus arteriosus are standard in term and preterm infants who are medically unstable. Beyond the newborn period, most centers now occlude the ductus with a percutaneously inserted vascular umbrella or using coils for smaller PDAs. In stable patients who are not candidates for an interventional cardiology approach (by nature of the length of the PDA), video-assisted thoracoscopic surgery (VATS) can be utilized.[93] Advantages of VATS compared with open thoracotomy include decreased postoperative pain, shorter hospital stay, and decreased incidence of chest wall deformity.[94]

Healthy asymptomatic patients undergoing surgery can be extubated in the operating room, allowing many options for anesthetic management. However, the fragile premature infant with severe lung disease may require mechanical ventilation for protracted periods after ligation of the ductus arteriosus. Fentanyl, pancuronium, oxygen, and air constitute a common anesthetic regimen for this procedure.[95] Many centers will bring the operative room environment to this patient population, performing the surgical ligation in the neonatal intensive care unit. Management of the premature infant in the operating room requires special considerations of gas exchange, hemodynamic performance, temperature regulation, metabolism, and drug and oxygen toxicity. Thoracotomy and lung retraction usually decrease lung compliance and increase oxygen and ventilatory requirements. A transient rise in systemic blood pressure with ligation of the ductus arteriosus may increase LV afterload or elevate cerebral perfusion pressure to the detriment of a premature patient. Inadvertent ligation of the left pulmonary artery or descending aorta has occurred because the ductus arteriosus often is the same size as the descending aorta.

The ductus is located near the recurrent laryngeal nerve (RLN), which may be damaged during the procedure. In addition to the close relationship of the RLN to the PDA and descending aorta, the RLN has a variable course that may be difficult to identify during dissection. Prior reports of PDA ligation performed by open thoracotomy indicate that the incidence of RLN injury is 1.2% to 8.8%.[96,97] RLN paralysis causes hoarseness and is not detected until the endotracheal tube is removed. The incidence may be reduced by location of the RLN within the thorax prior to ligation or clip placement using direct intraoperative stimulation of the RLN and evoked electromyogram monitoring.[98]

Ligation of an isolated ductus arteriosus generally results in normal cardiovascular function and reserve several months postoperatively.[99]

Atrial Septal Defect

Pathophysiology

There are three anatomic varieties of ASD. The most common, ASD secundum, is a defect in the septum primum, which ordinarily covers the region of the foramen ovale. ASD primum is a defect of the inferior portion of the atrial septum (endocardial cushion) usually accompanied by a cleft in the anterior leaflet of the mitral valve. Sinus venous defects are located near the junction of the right atrium and the SVC or IVC. They frequently are associated with a partial anomalous pulmonary venous connection.

Left-to-right shunting (simple) occurs at the atrial level, causing right ventricular volume overload. The degree of atrial level shunting is a function of the difference between right and left ventricular compliance as opposed to atrial pressure differential. Pulmonary blood flow is increased, but generally not enough to make these patients symptomatic during early childhood. However, later in life, as the left ventricle becomes less compliant and the LA pressures increase, the left-to-right shunt and volume load increase and symptoms of CHF may occur. In rare patients the long-standing increase in pulmonary blood flow causes pulmonary vascular obstructive disease.[100] Other problems associated with long-standing volume load from an atrial septal defect include atrial fibrillation.

Critical Care Management

The defect can be closed primarily with sutures or, if it is sufficiently large, with a synthetic patch. Sinus venosus defects associated with partial anomalous pulmonary venous connection require a more extensive patch that also directs the partial anomalous pulmonary venous return into the left atrium. These patients are among the healthiest encountered in the cardiac intensive care unit. Their anesthesia can be managed in many ways, but early tracheal extubation is the norm. Atrial arrhythmias, including atrial flutter and atrial fibrillation, are rarely seen during the postoperative period. Mitral regurgitation may occur in patients who have undergone repair of an ASD primum. Although transient LV failure has been reported, these patients rarely require inotropic support. Residual ASDs are uncommon, but occasionally failure to recognize partial anomalous pulmonary venous return results in a residual left-to-right shunt. Most patients can be extubated during the immediate postoperative period or in the operating room. With the exceptions mentioned, these patients usually have nearly normal cardiovascular function and reserve after repair.

Ventricular Septal Defect

Pathophysiology

Defects in the ventricular septum occur at several locations in the muscular partition dividing the ventricles. Simple shunting occurs across the ventricular septum. The magnitude of pulmonary blood flow is determined by the size of the VSD and the

PVR.[101] With a nonrestrictive defect, high LV flows and pressures are transmitted to the pulmonary artery. Therefore surgical repair is indicated within the first 2 years of life to prevent the progression of pulmonary vascular obstructive disease.[102] In patients with established pulmonary vascular disease, the pulmonary arteriolar changes may not recede when the defect is closed. In such cases, there may be progressive PVR elevation.[103,104] The growth and development of the pulmonary vascular bed are significant factors in the patient's ability to normalize pulmonary vascular hemodynamics after surgery.[104] When PVR approaches or exceeds systemic vascular resistance, right-to-left shunting occurs through the VSD and the patients develop progressive hypoxemia (Eisenmenger syndrome). Closing the VSD in this circumstance adds the risk for acute right heart failure to that of progressive increases in PVR.

Critical Care Management

Closure of a VSD necessitates CPB. The most common septal defect, the membranous defect, is often repaired through the TV from a right atriotomy. However, lesions in the inferior apical muscular septum or those high in the ventricular outflow tract may require a left or right ventriculotomy. If so, postoperative ventricular function may be impaired. Concomitant RV muscle bundle resection can further impair ventricular function.

Before repair, measures that decrease PVR may appreciably increase left-to-right shunting in patients with a nonrestrictive defect and may increase the degree of CHF. Postoperative RV or LV failure may be a manifestation of the preoperative status of the myocardium, a result of the ventriculotomy and CPB, or both. Small infants who fail to thrive, who are malnourished, and who have significant CHF preoperatively may have excessive lung water and may require prolonged mechanical ventilation postoperatively.[105] Such infants may have limited intraoperative tolerance for anesthetics that depress the myocardium or for maneuvers that increase pulmonary blood flow.

Persistent CHF and an audible murmur postoperatively, evidence of low cardiac output, or the need for extensive inotropic support intraoperatively suggests that a residual or previously unrecognized additional VSD is continuing to place a volume and pressure load on the ventricles. When PVR is increased preoperatively, the increase in RV afterload caused by closure of the VSD may be poorly tolerated, leading to the need for inotropic support of the heart and measures to decrease PVR.

Rarely, ventricular outflow tract obstruction is caused by placement of the septal patch. Transesophageal echocardiography performed in the operating room is an important tool in diagnosing this problem so it can be addressed prior to complete separation from CPB. Aortic regurgitation caused by prolapse of one of the aortic valve cusps can develop in subaortic or subpulmonic VSDs. In addition, heart block may occur after patch closure of a VSD. Temporary pacing may be needed to maintain an adequate heart rate and cardiac output. Generally, a permanent pacemaker is indicated when there is evidence of pacemaker dependence beyond 7 to 10 days.[106]

Critical Care Management for Late Postoperative Care

In the absence of residual VSDs, outflow obstruction, or heart block, most of these

patients regain relatively normal myocardial function, especially if the VSD is repaired early.[107] However, a small percentage of patients, especially those in whom a large defect was repaired late in childhood, continue to have some degree of ventricular dysfunction and some pulmonary hypertension.[108]

Atrioventricular Canal Defects

Pathophysiology

The endocardial cushion defect, or complete common AV canal, consists of defects in the atrial and ventricular septa and the AV valvular tissue. All four chambers communicate and share a single common AV valve. The atrial and ventricular shunts communicate volume and systemic pressures to the right ventricle and pulmonary artery. The ventricular shunt orifice usually is nonrestrictive (simple shunt); therefore PVR governs the degree of excess pulmonary blood flow. Left AV valve regurgitation and direct left-ventricular-to-right-atrial shunting may further contribute to atrial hypertension and total left-to-right shunting.

Critical Care Management

Surgical repair of this lesion consists of division of the common AV valve and closure of the ASD and VSD with either a single-patch or two-patch repair technique. In addition, the left AV valve (and sometimes the right AV valve) requires suture approximation and resuspension of the separated portions.

Prior to surgical repair, these patients have large left-to-right shunts. As a result of their high pulmonary blood flows, they have CHF and pulmonary hypertension. Myocardial depressants and therapies that decrease PVR while increasing shunt flow may be poorly tolerated before repair. Some patients, especially older children, may have obstructive pulmonary vascular disease. All of the potential complications of ASD and VSD closures are seen in these patients. In addition, the left AV valve may be severely regurgitant.[109] Inotropic support for the failing heart, afterload reduction for mitral regurgitation, and measures to decrease PVR may be required intraoperatively and postoperatively after repair.

Patients with trisomy 21 frequently have an associated complete AV canal. Measures to decrease PVR and the use of prolonged ventilatory support are often necessary because of their tendency toward upper airway obstruction and abnormal pulmonary vascular reactivity. The large tongue, hypotonia, upper airway obstruction, and difficult vascular access of these patients pose additional problems. The most frequent postoperative problems in patients with trisomy 21 are residual VSDs, left AV valve insufficiency, and pulmonary hypertension.[110]

Truncus Arteriosus Communis

Pathophysiology

With truncus arteriosus communis, the embryonic truncus fails to separate normally into the two great arteries. A single great artery leaves the heart and gives rise to the coronary, pulmonary, and systemic circulations. The truncus straddles a large VSD and receives blood from both ventricles.

Complete mixing of systemic and pulmonary venous blood in the single great

artery causes mild hypoxemia. Both pulmonary arteries usually originate from the ascending truncus, but occasionally only a single PA originates from the common trunk; the pulmonary artery orifice is seldom restrictive. The resulting shunt (simple) produces excessive pulmonary blood flow early in life as the PVR decreases. This *pulmonary steal* may elevate the arterial oxygen saturation and decrease the systemic blood flow. In such a case, net systemic oxygen transport decreases and lactic acidosis develops. Children with truncus arteriosus are at risk for developing early pulmonary vascular obstructive disease.[111] Regurgitation of blood through the truncal valve may place an additional volume load on the ventricles.

Critical Care Management

Complete repair of this lesion should be performed early, even in the neonate, before the development of irreversible pulmonary vascular changes.[112] The VSD is closed with a synthetic patch, and the pulmonary arteries are detached from the truncus. Continuity is established between the right ventricle and the pulmonary arteries with a valved conduit.[113] The truncal valve may require valvuloplasty if a significant amount of blood regurgitates through it. The presence of a dysplastic and moderately regurgitant truncal valve poses additional challenges; most data suggest that these patients are best served long term by cardiac transplantation. Pulmonary arterial banding or valve replacement may be considered as an interim bridging strategy to this destination.

Critical care management centers on control of pulmonary blood flow and ventricular support. Pulmonary blood flow may increase further with anesthetic agents, hyperventilation, alkalosis, and oxygen administration, resulting in hypotension and acute ventricular failure. If measures for increasing PVR do not decrease pulmonary flow, temporary occlusion of one branch of the pulmonary artery with a tourniquet limits pulmonary flow and restores systemic perfusion pressure until CPB can be instituted. Because these patients are often in high-output CHF, myocardial depressants should be used with caution.

Immediately after repair, the combination of persistent pulmonary arterial hypertension and RV failure can be fatal. Hence, aggressive measures should be taken to provide adequate myocardial function and lower PVR. A residual VSD adds volume and pressure load on the ventricles and may have a devastating impact on the patient's hemodynamics and oxygenation. A VSD should be suspected in patients who are not doing well postoperatively. Any residual VSD should be repaired if feasible. Truncal valve regurgitation or stenosis may induce LV failure early during the postoperative period.

Critical Care Management for Late Postoperative Care

Obstruction of the pulmonary conduit and the accompanying RV hypertension may occur early or late during the postoperative course. Usually the conduit is unable to support flow in the growing child after several postoperative years. Late development of truncal (aortic) valve regurgitation is possible. For patients who underwent repair later in childhood, residual persistent pulmonary hypertension may be a problem.

Total Anomalous Pulmonary Venous Connection

Pathophysiology

Patients with TAPVC are cyanotic because their pulmonary veins connect to a systemic vein (complete mixing) and they have various degrees of pulmonary venous obstruction. The venous connection may be supracardiac (eg, to the SVC, innominate, or azygos vein), cardiac (eg, to the coronary sinus), or infracardiac (eg, to the hepatic veins, portal vein, or ductus venosus). Patients with this anomaly must have a patent foramen ovale or an ASD that allows blood flow to the left side of the heart.

This anatomic arrangement provides complete mixing of all systemic and pulmonary venous blood in the right atrium. Unless there is significant stenosis of the pulmonary venous connection, most of this right atrial blood passes through the right ventricle into the pulmonary artery, which increases pulmonary blood flow. If pulmonary venous return is significantly diminished due to obstruction, there is increased pulmonary venous congestion and decreased pulmonary blood flow.

Critical Care Management

These patients may be very ill, with hypoxemia, severe pulmonary edema, and pulmonary artery hypertension. Resuscitation, including mechanical ventilation, positive end-expiratory pressure (PEEP), and inotropic support of the myocardium, is followed by early surgical intervention to relieve the pulmonary venous obstruction. Although patients are hypoxemic, their primary pathology is caused by obstructed venous return from the lungs. Therapy that increases pulmonary blood flow (eg, PGE_1 or NO) must be avoided. Surgical repair of TAPVC requires attachment or redirection of the pulmonary venous confluence to the left atrium.

Intraoperative and postoperative problems often are related to residual or recurrent stenosis of the pulmonary veins. In patients who have severe preoperative pulmonary venous obstruction, the pulmonary vascular bed is poorly reactive, reflected by highly pulmonary vascular resistance indices (PVRi). This elevation in PVRi results in high pulmonary artery pressures and poor RV function after bypass and during the early postoperative period. Critical care management of these patients after completion of the repair should emphasize inotropic support of the right ventricle, avoidance of myocardial depressant drugs, and minimization of PVR. Prolonged mechanical ventilation with gentle hyperventilation and other postoperative therapy to decrease PVR are required. Inhaled NO has been particularly useful in this population, provided there is no residual pulmonary vein obstruction.[50]

Critical Care Management for Late Postoperative Care

Other than the potential for late development of recurrent pulmonary venous obstruction, these patients generally do well and have good cardiovascular reserve once recovery from the surgery is complete.[114] The size of the pulmonary veins at birth may be a predictor of late complications with recurrent pulmonary vein stenosis.[115]

Transposition of the Great Arteries

Pathophysiology

With transposition of the great arteries, the right ventricle gives rise to the aorta. Almost 50% of patients with this anomaly have a VSD, and some of them have a variable degree of subpulmonic stenosis. Oxygenated pulmonary venous blood returns to the left atrium and is recirculated to the pulmonary artery without reaching the systemic circulation. Similarly, systemic venous blood returns to the right atrium and ventricle and is ejected into the aorta again. Obviously, this arrangement is compatible with life only for a few circulation times unless there is some mixing of pulmonary and systemic venous blood via a PDA or an opening in the atrial or ventricular septum at birth. The physiologic disturbance in these patients is one of inadequate mixing of pulmonary and systemic blood rather than one of inadequate pulmonary blood flow.

Mixing of blood at the atrial level can be improved by balloon atrial septostomy. If dangerous levels of hypoxemia persist after the septostomy and metabolic acidosis ensues, an infusion of PGE_1 can maintain the patency of ductus arteriosus, increase pulmonary blood flow (by increasing left-to-right shunting across the PDA), and thereby increase the volume of oxygenated blood entering the left atrium. The volume-overloaded left atrium is likely to shunt part of its contents into the right atrium and thereby improve the oxygen saturation of aortic blood. Unlike other lesions, increased left-to-right shunting of blood during anesthesia improves arterial oxygen saturation before correction of the transposition.

Depending on the particular anatomy and the presence of a VSD or pulmonary stenosis, one of three corrective procedures is used. The intraoperative and postoperative problems encountered differ with each type of procedure.

Atrial Switch Procedure (Mustard and Senning)

An atrial level partition is created with baffling to redirect pulmonary venous blood across the TV to the right ventricle and thus to the aorta.[116] Systemic venous (SVC and IVC) return is directed across the atrial septum to the mitral valve, into the left ventricle, and out the pulmonary artery. Although the pulmonary and systemic circuits are then connected serially instead of in parallel, this arrangement leaves the patient with a morphologic right ventricle and tricuspid valve in continuity with the aorta. Therefore this ventricle must work against systemic arterial pressure and resistance.

One problem with atrial baffles is that they can obstruct systemic and pulmonary venous return.[117] When this occurs, the patient manifests signs and symptoms of systemic venous obstruction, as evidenced by signs of systemic venous hypertension. Often an overt SVC syndrome is avoided as the surgical technique focuses on leaving the IVC baffle unobstructed. As a result an SVC obstruction can be decompressed via the azygous vein into the IVC. When the pulmonary venous pathway is obstructed, pulmonary venous hypertension may be manifested by respiratory failure, poor gas exchange, and pulmonary edema. Severe pulmonary venous obstruction is manifested in the operating room by the presence of copious amounts of bloody fluid in the endotracheal tube, low cardiac output, and frequently poor oxygenation. Residual interatrial shunts also may cause intraoperative or postoperative hypoxemia. Long-term rhythm disturbances and the limitations of ventricular and AV valve function have made this operation nearly obsolete.

Arterial Switch Operation (Jatene Procedure)

Because of the complications associated with atrial baffle procedures, Jatene and others explored whether anatomic correction of this lesion, by dividing both great arteries and reattaching them to the opposite anatomically correct ventricle, would improve survival.[118,119] This procedure requires excision and reimplantation of the coronary arteries to the neoaorta (formerly the proximal main pulmonary artery). The success of the arterial switch procedure depends on adequate preparation of the left ventricle and technical proficiency with the coronary transfer. Anatomic correction of transposition of the great vessels is done during the neonatal period when PVR (LV afterload) and LV pressure are high. Left ventricular mass decreases progressively after birth in this lesion with the physiologic drop in PVR. If the left ventricle's ability to tolerate the work required is misjudged, the child may develop severe LV failure postoperatively necessitating significant vasoactive or mechanical support to maintain cardiac output. Infants with transposition of the great arteries who are older than a few weeks of age with an intact ventricular septum may have decreased LV pressure and mass. In such cases, the left ventricle may not tolerate the work required to perfuse the systemic vessels. However, if the neonate has a nonrestrictive VSD, the left ventricle is accustomed to high systemic resistances and will tolerate the increased workload at any age. In older patients with an intact ventricular septum, banding the pulmonary artery can prepare the left ventricle to function as a systemic ventricle by increasing its afterload and muscle mass. If the left ventricle is “conditioned” by banding the pulmonary artery and augmenting pulmonary blood flow with a modified Blalock-Taussig shunt, then an arterial switch procedure usually can be accomplished 1 week later, after hypertrophy and hyperplasia have occurred.[120] However, during this interval, these patients are cyanotic, with a volume-loaded right ventricle and a pressure-loaded left ventricle, and they may require considerable pharmacologic support.[121]

In experienced centers, the incidence of mortality after neonatal repair of transposition of the great arteries now is less than 3% and may be less than 2% for most anatomic arrangements of coronary arteries if the aortic arch is normal.[122] Mid- and longer term outcomes for the ASO are excellent demonstrating a 25-year survival and freedom from reoperation rates of 96.7% and 75%, respectively.[123] Alternative operations are reserved almost exclusively for patients with particularly difficult coronary anatomy[124,125] or pulmonic (neoaortic) stenosis.

Myocardial ischemia or infarction may occur after mobilization and reimplantation of the coronary arteries, especially if they are stretched or twisted. Inotropic support, maintenance of coronary perfusion pressures, control of heart rate, and treatment with vasodilators may be particularly useful, as in adult patients with myocardial ischemia. Postoperative bleeding and tamponade occur more commonly with this operation because of the presence of multiple arterial anastomoses.

Ventricular Switch (Rastelli Procedure)

This procedure can be used in TGA with VSD or double-outlet right ventricle when there is an unrestrictive outlet VSD and when coexisting pulmonary valve stenosis precludes a standard arterial switch operation. The pulmonary valve is oversewn and the right ventricle is connected to the pulmonary artery with a conduit.[126]

Complications of the Rastelli procedure include obstruction of LV outflow as a result of narrowing of the subaortic region by the VSD patch. The conduit also may

obstruct during or after the immediate postoperative period. A small but significant incidence of heart block in these patients can be a difficult postoperative problem.

Critical Care Management

Management of patients following an atrial switch procedure rests on optimizing systemic oxygen delivery, monitoring for signs of baffle obstruction, and control of atrial arrhythmias. Most patients post-ASO without a VSD usually have an unremarkable postoperative course. Persistent ventricular dysfunction heralded by left atrial hypertension, hemodynamic instability, ventricular arrhythmia, or evidence of ischemic changes should prompt an intensive evaluation of the adequacy of the coronary anastomosis. Any of these perioperative issues or the unanticipated need for extracorporeal support necessitates immediate coronary evaluation and revision. Patients with delayed intervention (either due to late presentation or comorbidities that preclude a standard ASO timing of 2-10 days) usually will need to have a careful assessment for possible LV insufficiency. An aggressive strategy of systemic afterload reduction, deep sedation, and muscle relaxation while expecting a more protracted ICU course is often the norm for such patients. Occasionally, these patients will benefit from the use of ECLS or temporary left ventricular assist device (LVAD) support for retraining of the LV in the postoperative course.

Late Complications

Patients who have both a pulmonary ventricle and a morphologic right ventricle remaining as the systemic ventricle (ie, post-atrial baffle) can be regarded as having a physiologic or functional two-ventricle repair. Actuarial survival rates at 15 years have been quoted up to 85%; however, significant long-term functional deterioration is likely with increasing risk for right heart failure, sudden death, and dysrhythmias.[127,128] This situation is evidenced by systemic (right) ventricular dysfunction and TV regurgitation long after the repair.[129] These patients also are prone to develop significant atrial dysrhythmias, including supraventricular tachyarrhythmias and sick sinus syndrome later in life.[130] The arrhythmias may be preceded by RV dysfunction but also may be an isolated finding and are potentially the major cause of sudden death in these patients. A number of large follow-up series have reported that the probability of a patient remaining in sinus rhythm after an atrial level repair is 50% at 10 years and 40% at 20 years. Function of the sinus node may be seriously impaired by the atrial manipulations during surgery, and sick sinus syndrome (requiring pacemaker insertion) may occur late in the postoperative period. The atrial baffle provides a functional repair, although despite this result, many patients continue to maintain relatively active lives with few subjective symptoms. Objective exercise testing on intermediate and late follow-up may demonstrate limited RV reserve in as many as 50% of patients. Exercise duration, peak heart rate response, and peak minute oxygen consumption are reduced compared with age-matched controls.[131]

Virtually all coronary artery patterns are amenable to ASO. No particular pattern has been associated with late death. A report of coronary artery angiography in 366 patients following ASO (median age at follow-up 7.9 years) revealed coronary artery stenosis or occlusion in 3% of patients.[132] The long-term significance of these

coronary artery abnormalities has not been determined. Despite the angiographic findings, evaluation with serial ECG, exercise testing, and wall-motion abnormalities on echocardiography rarely demonstrate evidence of ischemia.[133]

After repair, the *native* pulmonary valve becomes the *neoaortic* valve. A 30% incidence of trivial-to-mild aortic regurgitation has been reported on intermediate-term follow-up, without significant hemodynamic changes.[134] Severe regurgitation is unusual.

There appears to be a very low incidence of significant rhythm disturbances after ASO.[135] Supravalvar pulmonary artery stenosis was an early complication but now is less common with surgical techniques that extensively mobilize, augment, and reconstruct the pulmonary arteries. Supravalvar AS may develop but is rare.

Assessment of myocardial performance using echocardiography, cardiac catheterization, and exercise testing following ASO has demonstrated function identical to that in age-matched controls. Based on the currently available clinical, functional, and hemodynamic data, a patient who has undergone ASO with no evidence of subsequent problems should be treated as any patient with a structurally normal heart when presenting for noncardiac surgery.

Late complications of the Rastelli procedure include progressive conduit obstruction and RV hypertension, residual VSDs, and occasionally subaortic obstruction from diversion of LV outflow across the VSD to the aorta.

Tetralogy of Fallot

Pathophysiology

The four anatomic features of TOF are VSD, RV outflow tract obstruction, overriding of the aorta, and RV hypertrophy. In addition, there may be VSDs of the muscular region of the septum and right-sided obstruction of the pulmonary valve and the main and branch pulmonary arteries.

Resistance to RV outflow forces systemic venous return from right to left across the VSD and into the aorta, producing arterial desaturation. The amount of blood that shunts right to left through the VSD varies with the magnitude of the RV outflow tract obstruction and with SVR. Distal PVR is low and has minimal influence on shunting. Systemic vasodilation, in conjunction with increasing dynamic infundibular stenosis, intensifies right-to-left shunting and can lead to hypercyanotic *spells*. Such spells can occur at any time before surgical correction of the anomalies and can be life threatening. Because the morbidity associated with recurrent hypercyanotic spells is significant, many physicians consider recurrent episodes of hypercyanosis an indication for corrective surgery at any age.

Critical care management of TOF patients with hypercyanotic episodes should focus on minimizing oxygen consumption, acidosis, tachycardia, and PVR while augmenting preload and SVR. Hypercyanotic spells in nonanesthetized children should initially be managed with 100% oxygen by facemask, a knee-chest position or squat position (to increase SVR), and morphine sulfate. This regimen can usually stabilize the dynamic infundibular stenosis while keeping SVR elevated. Deeply cyanotic and lethargic patients are given rapid IV crystalloid infusions to augment circulating blood volume. Continued severe hypoxemia is treated with a vasopressor bolus (eg, phenylephrine 1–2 μg/kg) to increase SVR and sometimes with judicious use of IV propranolol or esmolol to slow the heart rate. The latter allows more filling

time and relaxes the infundibulum. If a hypercyanotic spell persists despite treatment, immediate surgical correction of the anomaly is indicated. The child can be anesthetized with IV narcotics, and an inhalation agent such as halothane may be beneficial to reduce hyperdynamic outflow tract obstruction. Anesthetic agents that predominantly decrease SVR, such as isoflurane, should be used with caution. The pattern of mechanical ventilation is critical, as excessive intrathoracic pressure can further reduces antegrade flow across the RV outflow.

Critical Care Management for the Early Postoperative Course

The surgical approach to the patient with TOF who presents with recurrent early hypercyanotic spells is variable. The traditional approach is to defer a complete repair until the standard elective repair can be completed (3-6 months of age). Delayed repair also is often necessary when a coronary artery crosses the RV outflow tract precluding transannular patch repair. There are currently two palliative interventions to facilitate a delayed repair strategy. The first is the use of a systemic-to-pulmonary artery shunt. Excellent outcomes have been achieved with this approach, and the need for a transpulmonary valve annulus outflow patch (transannular patch) at the time of definitive surgery is reduced.[136] The risks of cyanosis and complications related to a systemic-to-pulmonary artery shunt argue for early complete repair of TOF. The alternative approach, developed more recently, is stenting the RV outflow tract in the cardiac catheterization laboratory.[137] This procedure has the additional benefit of improving pulmonary artery growth prior to the definitive repair. Dohlen and colleagues reported on a series of nine patients who were effectively palliated with this approach at median age of 3 weeks.[138]

Another approach for patients with TOF is to proceed with an early complete repair. For that method, a ventriculotomy is performed in the RV outflow tract and frequently is extended distally through the pulmonary valve annulus and beyond any associated pulmonary artery stenosis. The outflow tract is enlarged with pericardium or synthetic material, and obstructing muscle bundles are resected to relieve the outflow tract obstruction.[139] Because they are smaller and younger, these patients may be at increased risk for complications associated with CPB. Pulmonary regurgitation results after a transannular incision that may compromise ventricular function in the postoperative period. In approximately 8% of patients, abnormalities in the origin and distribution of the coronary arteries preclude placement of the RV outflow patch, making it necessary to bypass the stenosis by placing an external conduit from the body of the right ventricle to the pulmonary artery.[140,141] An analysis of 3059 TOF repairs between 2002 and 2007 demonstrated that 83% (2534) had a complete repair as their initial index procedure (with 6%, 19%, 38%, and 24% undergoing operation at the ages of 0 to 1, 1 to 3, 3 to 6, and 6 to 12 months, respectively).[142] There were 217 (7%) patients who underwent complete repair following an initial palliation. Rates of ventriculotomy, transannular patch, and RV-PA conduit use were significantly higher in those requiring an initial palliation. Discharge mortality was higher in palliative patients versus initial complete repair (7.5% versus 1.3%). There was less disparity in discharge mortality between the two approaches among neonates (6.2% versus 7.8%).[142]

When weaning patients from CPB following TOF repair, the aim of therapy is to support RV function and minimize afterload on the right ventricle. This is

particularly important following repair in neonates or small infants. Although systolic dysfunction of the right ventricle may occur following neonatal ventriculotomy, more commonly the clinical picture is one of a *restrictive physiology* reflecting reduced RV compliance or diastolic function.[30,31] Factors contributing to diastolic dysfunction include ventriculotomy, lung and myocardial edema following CPB, inadequate myocardial protection of the hypertrophied ventricle during aortic cross-clamp, coronary artery injury, residual outflow tract obstruction, volume load on the ventricle from a residual VSD or pulmonary regurgitation, and arrhythmias.

Patients usually separate from CPB with a satisfactory blood pressure and atrial filling pressures less than 10 mm Hg on modest inotropic support, such as milrinone of 0.5 μg/kg/min or dopamine 5 to 10 μg/kg/min. However, in neonates during the first 6 to 12 hours after surgery, a low cardiac output state with increased right-sided filling pressures from diastolic dysfunction is common following a right ventriculotomy, and continued sedation and paralysis usually are necessary for the first 24 to 48 hours to minimize the stress response and associated myocardial work. Preload must be maintained, despite elevation of RA pressure.

In addition to high right-sided filling pressures, pleural effusions or ascites may develop. Significant inotropic support is often required, and a phosphodiesterase inhibitor, such as milrinone, is beneficial because of the lusitropic properties. Because of the restrictive physiology, even a relatively small volume load from a residual VSD or pulmonary regurgitation is often poorly tolerated in the early postoperative period, and 2 to 3 days may be required before RV compliance improves and cardiac output increases. Although the patent foramen ovale or any ASD usually is closed at the time of surgery in older patients, it is beneficial to leave a small atrial communication following neonatal repair. In the face of diastolic dysfunction and increased RV end-diastolic pressure, a right-to-left atrial level shunt maintains preload to the left ventricle and therefore cardiac output. Patients may be desaturated initially following surgery because of this shunting. As RV compliance and function improve, the amount of shunt decreases and both antegrade pulmonary blood flow and systemic arterial oxygen saturation increase.

Arrhythmias following repair include heart block, ventricular ectopy, and junctional ectopic tachycardia. Maintaining sinus rhythm is important to optimize end-diastolic filling and minimize end-diastolic pressure. Atrioventricular pacing may be necessary for heart block. Complete right bundle branch block is typical on the postoperative ECG.

Most patients recover systolic ventricular function postoperatively. However, in a small group of patients, especially those repaired at older ages, significant ventricular dysfunction remains.[143,144] These patients can have left ventricular sub-endocardial ischemia that impairs LV myocardial mechanics.[145] Pulmonary valve insufficiency may contribute to residual ventricular systolic dysfunction.[146] The most common cause of systolic dysfunction immediately after repair of CHD is a residual or previously unrecognized VSD, which causes a volume load on the left ventricle and pressure load on an already stressed right ventricle, leading to RV failure and poor cardiac output.[27] A residual VSD combined with residual RV outflow obstruction is particularly deleterious.

In some patients, the distal pulmonary arteries may be so hypoplastic and stenotic that they cannot be satisfactorily corrected. Suprasystemic pressure develops in the right ventricle, which in some cases can be ameliorated by partially opening the VSD

to allow an intracardiac right-to-left ventricular shunt. This shunt unloads the compromised right ventricle at the expense of decreased arterial oxygen saturation.

Critical Care Management for Late Postoperative Care

Reconstruction of the RV outflow tract may lead to significant problems that affect RV function and risk for arrhythmias over time. Although most of the long-term outcome data pertain to patients following TOF repair, similar complications and risks are likely for those who have undergone an extensive RV outflow reconstruction, such as placement of a conduit from the right ventricle to the pulmonary artery for correction of pulmonary atresia, truncus arteriosus, and the Rastelli procedure for transposition of the great arteries with pulmonary stenosis.

Complete surgical repair of TOF has been successfully performed for more than 40 years, with studies reporting a 30- to 35-year actuarial survival of approximately 85%.[147] Many patients report leading relatively normal lives, but RV dysfunction may progress after repair and may be evident only on exercise stress testing or echocardiography. A spectrum of problems may develop, ranging from a dilated right ventricle with systolic dysfunction to diastolic dysfunction from a poorly compliant right ventricle, and these problems must be thoroughly evaluated preoperatively. In addition, continued evaluation is necessary because of the increased risk for ventricular arrhythmias and late sudden death. Factors that may adversely affect long-term survival include older age at initial repair, initial palliative procedures, and residual chronic pressure or volume load as occurs from pulmonary insufficiency or stenosis.

Systolic dysfunction secondary to a residual volume load from pulmonary regurgitation after tetralogy repair is a predictor of late morbidity. It is reflected as cardiomegaly on chest radiograph, an increase in RV end-diastolic volume and regurgitant volume by echocardiography and cardiac MRI,[17] and a reduction in anaerobic threshold, maximal exercise performance, and endurance on exercise testing.[148] Patients who have significant pulmonary regurgitation, RV dilation, and reduced RV function are at potential risk for a fall in cardiac output during anesthesia, particularly as positive pressure ventilation may increase the amount of regurgitation.

An important group to distinguish consists of those who have continued restrictive physiology or diastolic dysfunction secondary to reduced ventricular compliance. They usually do not have cardiomegaly, they demonstrate better exercise tolerance, and the risk for ventricular dysrhythmias is possibly decreased. Although the right ventricle is hypertrophied, function is generally well preserved on echocardiography, with minimal pulmonary regurgitation. The incidence of significant RV outflow obstruction developing over time is low. Residual obstruction contributes to early mortality within the first year after surgery but is well tolerated in the long term.

A wide variation in the incidence of ventricular ectopy has been reported in numerous follow-up studies, including up to 15% of patients on routine ECG and up to 75% of patients on Holter monitor. Multiple risk factors, including an older age at repair, extent of ventriculotomy, residual hemodynamic abnormalities, and duration of follow-up, have all been considered important. In common with these factors are probable myocardial injury and fibrosis from chronic pressure and volume overload, combined with cyanosis. Although ventricular ectopy is common in asymptomatic

patients during ambulatory ECG, Holter monitoring, and exercise stress testing, it often is low grade and does not identify those patients at risk for sudden death. Electrophysiologic induction of sustained ventricular tachycardia (VT), especially when monomorphic, is suggestive of the presence of a reentrant arrhythmic pathway. Although dependent on the stimulation protocol used to induce VT, the presence of monomorphic VT in a symptomatic patient with syncope and palpitations is significant and indicates treatment with radiofrequency ablation, surgical cryoablation, antiarrhythmic drugs, or placement of an implantable cardioverter-defibrillator.[149] The risk for ventricular dysrhythmias during anesthesia and ICU care for subsequent hospitalizations is unknown. Although preoperative prophylaxis with antiarrhythmic drugs is not recommended, a means for external defibrillation and pacing must be readily available.

Pulmonary Atresia

Pathophysiology

Atresia of the pulmonary valve or main pulmonary artery forms a spectrum of cardiac defects, the management of which depends on the extent of atresia, size of the right ventricle and tricuspid valve (TV), presence of a VSD and collateral vessels, surface area of the pulmonary vascular bed, and coronary artery anatomy. The timing of developmental abnormality defines the associated lesions. Pulmonary atresia with intact ventricular septum (PAIVS) is primarily an abnormality of tricuspid valve development that subsequently affects the pulmonary valve through its effects on fetal RV growth. Because the impact on the pulmonary valve is late, the fetal truncus arteriosus has already divided and the mesenchymal distal pulmonary vasculature can connect to a main pulmonary artery pressure head appropriately. As a result, this lesion predictably has well-developed central pulmonary arteries and pulmonary artery arborization.

At one end of the spectrum of PAIVS, platelike pulmonary atresia overlaps with critical pulmonary stenosis where there is a mild or negligible degree of hypoplasia of the right ventricle and TV. In these lesions, a fixed obligatory right-to-left atrial level shunt of all systemic venous return exists. Some blood may flow into the right ventricle, but because there is no outlet, blood regurgitates back across the TV and eventually reaches the left atrium and left ventricle. Pulmonary blood flow is derived exclusively or predominantly from a PDA. As a rule, these patients do not have extensive aortopulmonary collateral blood flow; consequently, they often become cyanotic when the PDA closes after birth. Critical pulmonary valve stenosis can be effectively treated by balloon valvuloplasty in the catheterization laboratory. Antegrade flow across the RV outflow may not improve immediately but may gradually increase over days as RV compliance improves. In platelike pulmonary atresia, radiofrequency perforation precedes balloon valvuloplasty.

Most patients with pulmonary atresia with intact ventricular septum have an underdeveloped TV and right ventricle. Depending on the degree of RV hypoplasia (which is directly related to the TV annulus Z score), the patient may be unsuitable for a biventricular repair in the long term. In this situation, initial palliation with an aortopulmonary shunt is necessary. Reconstruction of the RV outflow with a pericardial patch or interventional catheter techniques also may be considered if the right ventricle is of a sufficient size that a two-ventricle repair could be considered

(approach overlaps with platelike pulmonary atresia with some RV hypoplasia). A large conal branch or aberrant left coronary artery across the RV outflow tract may restrict the size of a ventriculotomy and placement of a patch or conduit. Patients with pulmonary atresia, a hypoplastic right ventricle, and intact ventricular septum may have numerous fistulous connections (sinusoids) between the small hypertensive RV cavity and the coronary circulation.[150] This is distinct from right ventricular dependent coronary circulation where these sinusoidal connections are additionally accompanied by proximal stenoses in the true coronary arteries. This is a distinct risk in patients with a TV annulus Z score <−3, but it has been documented in moderate RV hypoplasia.[151] If decompression of the RV outflow tract is being considered in this population, a coronary angiogram is highly desirable to exclude this phenomenon.

At the other end of the spectrum, severe pulmonary atresia may be associated with an extremely hypoplastic right ventricle that is not suitable for biventricular repair. A palliative procedure with a modified Blalock-Taussig or central shunt usually is necessary at first to improve pulmonary blood flow, followed by staged single-ventricle repair (see the "Fontan Procedure" section).

In contrast to PAIVS, PA/VSD and TOF with PA represent an early failure of proper conotruncal development. As a result, the mesenchymal segmental pulmonary arteries do not see the main pulmonary artery pressure head and instead form connections with the nearest alternative (aorta). This is the nature of the development of the aortopulmonary collaterals (APCs) associated with the lesion. If the collaterals are substantial, defining a large pulmonary arterial segment, they are referred to as major aortopulmonary collateral arteries or MAPCAs. As a rule, these patients have two good-sized ventricles (unless accompanied by other lesions, such as an unbalanced AV septal defect). This disease can exist in a spectrum with confluent central pulmonary arteries and a short-segment main PA atresia to discontinuous PAs without a true central PA.

In the former situation, the pulmonary artery arborization is often close to normal with few MAPCAs. When antegrade flow is established from the right ventricle into the main pulmonary artery by a reparative procedure, the left-to-right shunt via collateral flow will impose a diastolic load on the left ventricle. Preoperative occlusion of these collateral vessels can be accomplished by interventional techniques in the cardiac catheterization laboratory but may leave the child precariously cyanotic in the hours before operation. The alternative is to complete the surgical procedure in a hybrid suite. This lesion is completely repaired in the neonatal period.

As mentioned, MAPCAs may be present to varying degrees, supplying some or all segments of the lung. They can be associated with a large left-to-right shunt, contributing to volume overload and pulmonary hypertension. Larger collateral vessels supplying significant portions of the lung can be anastomosed or "unifocalized" to the native pulmonary arteries, with the ultimate aim being to establish full antegrade pulmonary blood flow. Smaller vessels to some segments of lung can be coiled in the cardiac catheterization laboratory, provided there is antegrade flow from the native pulmonary arteries to those lung segments (dual supply).

When the pulmonary arteries are diminutive, it is important to establish early antegrade flow from the RV to the PA, in an effort to promote growth and establish a

pathway to the pulmonary arteries for subsequent balloon dilation. A modified Blalock-Taussig or Mee shunt may initially be necessary to provide sufficient pulmonary blood flow if the pulmonary arteries are exceedingly small. Initially, the VSD can be left open, and postoperative management of cyanosis or CHF will be determined by the size of and the resistance offered by the pulmonary circulation. The course in these patients can be dynamic and demanding for even the most experienced practitioners. When collaterals are unifocalized in the operating room and right ventricle to diminutive pulmonary artery continuity is established, cyanosis may ensue and therapy is aimed at lowering PVR or (re)establishing adequate pulmonary blood flow. On the other hand, if the child is fully saturated in the aorta with elevated pulmonary artery oxygen saturation and LA pressure, then a left-to-right shunt through the VSD may be developing, which will produce a volume load on the left ventricle and an unstable postoperative course, dictating VSD closure. When the patient is not fully saturated in the aorta but is suffering from a volume-loaded left ventricle with low cardiac output and high LA pressure postoperatively, excessive systemic-to-pulmonary collaterals may be the culprits, requiring catheterization laboratory investigation and occlusion or immediate reoperation.

Critical Care Management

Critical care management of patients with pulmonary atresia is similar to that for TOF, except that hypercyanotic spells do not occur. Maintaining the patency of the ductus for the perioperative treatment of neonates with pulmonary atresia and critical pulmonary stenosis is essential. If there is platelike PA and the main pulmonary artery is present, it may be possible to perform a pulmonary valvotomy (interventional or surgical) and provide adequate pulmonary blood flow without a supplemental systemic-to-pulmonary artery shunt. The goal of therapy is to improve oxygenation and decrease RV afterload. Because the LV may be more pressure and volume loaded in this lesion than in the normal fetus, the RV may be relatively noncompliant postoperatively. This may manifest as requirements for high filling pressures and consequent right-to-left shunting through a purposefully patent foramen ovale. With growth and improved compliance of the right ventricle, the right-to-left shunting diminishes and the infant's oxygenation improves substantially. If hypoxemia persists, a PGE_1 infusion can be initiated to temporize either until accommodation of the restrictive RV physiology or for a Blalock-Taussig (BT) shunt.

In patients with long-segment pulmonary atresia, the need for a conduit to bridge the gap between the right ventricle and the pulmonary artery complicates the repair. Again, RV failure may occur postoperatively, especially when there is a residual VSD or RV outflow obstruction. The conduit may obstruct acutely during chest closure, further elevating pressure in the right ventricle. The relationship of the conduit to either normal or variant coronary anatomy is vital, as impingement of these structures can present as sudden inexplicable deterioration related to sternal closure.

After the VSD is closed and blood flow is from the right ventricle to the pulmonary arteries, there may be excessive pulmonary blood flow ($Qp/Qs > 1$) as a result of the combined flow into the pulmonary arteries from the right ventricle and

from aortopulmonary collaterals. If this occurs, the patient develops CHF and requires intraoperative inotropic support and an extended period of postoperative mechanical ventilation. With large collateral flow, the pulse pressure is wide and diastolic pressure low. The patient may require surgery to ligate the collateral vessels or may require embolization.

Critical Care Management for Late Postoperative Care

Patients with TOF and pulmonary atresia are subject to the same late problems and complications as patients with TOF alone. In addition, they will require conduit revisions over their lifetime. Some patients have accelerated conduit obstruction after surgery, which is often related to the presence of a porcine valve.[152] Consequently, many experts now prefer bovine-valved conduits or homografts except in a certain situations, such as when the distal pulmonary vascular impedence is high resulting in central pulmonary artery hypertension. In these situations a valve-less conduit that permits pulmonary insufficiency (and thus relieves central PA hypertension) is preferred. In cases when pulmonary regurgitant volume load to the RV is undesirable, some favor the placement of a heterologous bovine jugular vein bioprosthesis with a trileaflet venous valve.[153] This has been the valved conduit of choice in patients younger than 18 years of age, whenever pulmonary regurgitant volume load to the RV is undesirable.[153] Small-caliber bovine jugular vein conduits may result in significantly improved freedom from dysfunction at 5 and 10 years follow-up compared to pulmonary homografts in patients who received the operation during the first 2 years of life.[154]

Tricuspid Atresia

Pathophysiology

In this condition, an imperforate TV and hypoplasia of the right ventricle are present, often accompanied by a VSD of variable size and by pulmonic stenosis. The most common form of tricuspid atresia has normally related great arteries; when associated with transposition of the great vessels, the clinical presentation is similar to hypoplastic left heart syndrome.

In the usual type of tricuspid atresia, an obligatory atrial-level shunt exists from the right atrium through the patent foramen ovale or ASD into the left atrium, where complete mixing takes place. The degree of hypoxemia depends on the amount of pulmonary blood flow, which is regulated by the severity of the pulmonic stenosis. This in turn is regulated by the size of the VSD; patients with an extremely small/restrictive VSD will have pulmonary atresia in addition to tricuspid atresia. The common presentation is characterized by significant hypoxemia caused by the decreased pulmonary blood flow.

Critical Care Management

The ultimate palliative surgical course for tricuspid atresia is a modified Fontan procedure, but an initial palliative procedure may be required to improve pulmonary blood flow (modified BT shunt). Neonatal hypoxemia prior to surgery can be effectively stabilized on a PGE_1 infusion. A pulmonary artery band may be needed if the pulmonary blood flow is increased, or a shunt may have to be created

for the severely hypoxemic child with decreased pulmonary blood flow upon ductal closure. The critical care management and complications are those discussed in the sections on shunts, banding, and modified Fontan procedures. Complications of chronic hypoxemia and cyanosis are also present.

Left-Sided Obstructive Lesions

Pathophysiology

This category includes valvar, subvalvar, and supravalvar mitral and aortic stenosis (AS), aortic coarctation, IAA, and the HLHS. Although these lesions can occur as isolated defects, they often are accompanied by other congenital cardiac defects. Identification of additional structural defects is necessary for optimal preoperative, surgical, and postoperative treatment.

Patients with LV outflow tract obstruction tend to present as either neonates or young infants with significant LV dysfunction and CHF or later in childhood with subclinical LV hypertrophy. The dramatic presentation of a neonate with circulatory collapse typically occurs with lesions that obstruct systemic blood flow so severely that right-to-left shunting at the ductus arteriosus is required to perfuse the body. As the ductus significantly narrows or closes, the LV becomes acutely pressure overloaded and begins to fail, leading to pulmonary edema and respiratory distress. When systemic perfusion becomes inadequate, the patient develops hypotension, weak pulses, metabolic acidosis, and oliguria. Classic examples include severe (or "critical") valvar AS, coarctation of the aorta, and HLHS (see the earlier single-ventricle discussion).

If the obstruction is less severe, the child can make the transition through ductal closure without notable LV dysfunction and maintain an adequate cardiac output. Over time, however, the pressure overload on the LV stimulates generalized hypertrophy. If untreated and significant, long-term pressure overload can cause LV diastolic dysfunction (compliance falls and end-diastolic pressure rises, causing pulmonary edema), LV systolic dysfunction, and episodic myocardial ischemia. Clinical manifestations of these changes can include reduced exercise tolerance, exertional chest pain, ventricular dysrhythmias, syncope, and sudden death. Significant LV dilation or clinical signs of CHF are ominous findings associated with a poor prognosis and an increased surgical mortality rate.

Aortic Stenosis

Of the three anatomic subtypes of AS, valvar AS occurs more frequently than subvalvar or supravalvar AS. The newborn with critical valvar AS who develops hypotension and acidosis as the ductus arteriosus closes requires resuscitation with PGE_1 to restore aortic flow plus mechanical ventilation and inotropic support to achieve stabilization before an intervention is performed. Currently, balloon dilation of the stenotic aortic valve during cardiac catheterization is the preferred intervention at most centers. A surgical valvotomy under direct vision using CPB is the surgical alternative. Despite successful relief of obstruction, significant LV dysfunction and low cardiac output often persist for days after the procedure and require continued treatment with mechanical ventilation and vasoactive drugs. Until LV function recovers and can support the entire cardiac output, continuation of

prostaglandin infusion may be necessary to maintain patency of the ductus arteriosus. Patients should be carefully evaluated after balloon aortic valvuloplasty for residual AS and aortic regurgitation, the chief potential complication of valve dilation, especially if cardiac output does not improve over several days.

Older infants, children, and adolescents with moderate (pressure gradient 50-70 mm Hg at catheterization) or severe (pressure gradient >70 mm Hg at catheterization) valvar AS also are generally good candidates for balloon aortic valvuloplasty. If more than mild aortic regurgitation coexists with AS, however, a surgical intervention is preferred to balloon valvuloplasty. The pathophysiology produced by all types of aortic outflow obstruction is similar—that is, the pressure-overloaded LV becomes progressively hypertrophied and develops reduced compliance and an abnormally elevated end-diastolic pressure.

Initial assessment of obstruction relief can occur when the patient is still in the catheterization laboratory or operating room by either direct pressure measurements or echocardiography. Nevertheless, reevaluation for residual obstruction by physical examination or echocardiography in the ICU as patients recover from anesthesia and baseline physiology returns is important because outflow gradients can change. A significant residual obstruction should be suspected in any patient with persistent low cardiac output following the intervention.

Poor recovery of LV function after surgery can occur secondary to inadequate myocardial protection with cardioplegia in hearts with significant ventricular hypertrophy. Patients with marked hypertrophy are also at greater risk for developing VT and ventricular fibrillation early after surgery.

In patients with preserved LV systolic function who undergo an uncomplicated procedure, such as aortic valvuloplasty or subvalvar membrane resection, myocardial recovery after CPB is typically rapid and inotropic support is usually not required. Systemic hypertension is more common following relief of LV outflow obstruction, especially during emergence from anesthesia and sedation.

Antihypertensive therapy in the initial 24 to 48 hours may be necessary to prevent an aortic suture line and reconstructed valve leaflet disruption from excessive stress and to allow adequate hemostasis. Both beta-blockers (eg, labetalol, propranolol, and esmolol) and vasodilators (eg, nitroprusside), alone or usually in combination, are effective for lowering blood pressure in these patients.

In addition to assessing aortic valve and LV function, an evaluation for complications specific to each procedure is required. For example, if a myectomy is performed as part of the resection of fibromuscular subvalvar AS, the possibility of a new VSD, mitral valve injury, and left bundle branch block should all be assessed. Following the Ross procedure, it is important to assess patients for RV outflow tract and LV outflow tract obstruction, because the RV outflow tract is also reconstructed with a valved conduit. This procedure involves reimplantation of the native coronary arteries into the new pulmonary autograft placed in the aortic position; signs of coronary ischemia, unexplained hemodynamic collapse, or ventricular arrhythmia should prompt aggressive reevaluation of coronary flow adequacy.

Coarctation of the Aorta

Coarctation of the aorta is a narrowing in the descending aorta located at the level of insertion of the ductus arteriosus (juxta- or contraductal coarctation). Narrowing of the aortic lumen is asymmetric, with the majority of the obstruction occurring

because of posterior tissue infolding, leading to the common description of a posterior aortic shelf. Depending on the severity and rapidity of development of the narrowing, patients can present as neonates with severe obstruction (a *critical* coarctation of the aorta) upon ductal closure, as infants with CHF, or as children/adolescents with asymptomatic upper extremity hypertension (especially with exercise).

Neonates presenting with critical coarctation of the aorta can often be distinguished clinically from patients with critical AS by their clearly discrepant upper versus lower body pulses, perfusion, and blood pressures. Other features at presentation, including evidence of CHF and inadequate blood flow to tissues, are similar. Because ductal narrowing or closure is common after hospital discharge, these patients often become critically ill and suffer end-organ damage before the ductus arteriosus can be reopened and resuscitation complete. Intestinal and renal ischemia leading to necrotizing enterocolitis and renal failure, respectively, are well-known complications of critical coarctation of the aorta. Echocardiography often reveals additional left-sided defects such as bicuspid aortic valve, valvar AS, aortic arch hypoplasia, and VSD. Preoperative stabilization and management in this clinical scenario includes initiation of PGE_1, mechanical ventilation, inotropic agents, and diuretic agents, as needed. In addition, these patients require adequate time for end-organ recovery before performing an intervention. In rare situations, the afterload on both ventricles cannot be relieved, as the PGE_1 infusion is unable to open the ductal and periductal arch tissue. In such a situation there is no prospect of facilitating cardiac and end-organ recovery; the patient should be taken to the operating room urgently for coarctation repair.

Coarctation of the aorta also occurs in association with complex defects such as D-transposition of the great arteries, single ventricle, and complete AV canal defect. If the ductus arteriosus is patent during echocardiographic evaluation of a neonate with suspected CHD, it often is not possible to predict the severity of coarctation of the aorta with confidence. A patient can have an abnormally narrowed aorta just proximal to the site of ductal insertion (ie, the aortic isthmus) and a posterior shelf but still not develop a severe coarctation of the aorta following ductal closure. Therefore evaluation of the potential severity of coarctation of the aorta in the ICU often involves discontinuing the PGE_1 infusion to allow for the ductus to close, followed by close clinical and echocardiographic reassessment for clinical manifestations of coarctation. An intervention to reduce aortic arch obstruction is indicated in any neonate with clinical or echocardiographic evidence of reduced ventricular function or impaired cardiac output related to coarctation development. These indications are more important than the systolic blood pressure difference between upper and lower body per se, although differences greater than 30 mm Hg often are accompanied by diminished ventricular function.

The postoperative management of patients following surgical repair of coarctation of the aorta can vary depending on the age at intervention. However, the key issues for assessment in all patients are adequate relief of obstruction and preservation of spinal cord function. Upper and lower body blood pressures and pulses should be compared serially and the lower extremities monitored closely for the return of sensation and voluntary movement in the early postoperative period. Equal pulses and a reproducible systolic blood pressure difference less than 10 to 12 mm Hg

between upper and lower extremities indicate an excellent repair. Neonates and young infants typically require 1 to 2 days of mechanical ventilation postoperatively. Older children and adolescents often can be extubated in the operating room and rarely require inotropic support. In fact, these patients repaired at an older age are increasingly likely to have significant hypertension,[155] which should be treated aggressively early after surgery to reduce the risk of aortic suture disruption and bleeding. Beta-blockers and vasodilators, along with adequate analgesia and sedation, are effective. Patients with long-standing coarctation of the aorta frequently have persistent systemic hypertension despite an adequate surgical repair; continued treatment with angiotensin-converting enzyme inhibitors is advocated to achieve normal blood pressures. Due to the challenges in managing this cohort of older patients after coarctation repair and the advent of interventional catheterization approaches including the use of covered stents, a surgical repair strategy is increasingly falling out of favor.

Four uncommon complications are associated with surgical repair of coarctation of the aorta. Postcoarctectomy syndrome manifests as abdominal pain or distension in older patients and is presumably caused by mesenteric ischemia from reflex vasoconstriction after restoration of pulsatile aortic flow. Recurrent laryngeal nerve and phrenic nerve trauma can cause vocal cord paralysis and hemidiaphragm paresis or paralysis, respectively, with neonates and infants at highest risk. Disruption of lymphatic vessels or thoracic duct trauma can produce a chylous effusion that may require treatment by drainage or dietary modification.

Catheter-directed balloon angioplasty is used to treat both native and residual coarctation of the aorta.[156] The results of native coarctation of the aorta dilation after early follow-up appear similar to published surgical results, but aortic aneurysm formation has been reported. Balloon angioplasty of recurrent coarctation of the aorta after surgery is effective and is generally preferred to reoperation.

Interrupted Aortic Arch

Patients with IAA typically present as neonates with either a loud systolic murmur or circulatory compromise as the ductus arteriosus closes. Therefore patient presentation can be similar to other severe left-sided obstructive lesions such as critical AS, critical coarctation of the aorta, and HLHS. Unlike either critical AS or coarctation of the aorta, however, severe pressure overload on the LV does not occur in the presence of an unrestrictive VSD, which functions as a “pop off” for LV outflow. The approach to resuscitation is similar to that described for the other ductal-dependent left-sided obstructive lesions, with attention to the possibility of pulmonary overcirculation as for HLHS.

Postoperative management issues specific to patients with IAA include assessment of possible residual left-sided obstruction, both in the aortic arch and in the subaortic region, shunting across a residual VSD, hypocalcemia (related to DiGeorge syndrome), dysrhythmias, and LV dysfunction with low cardiac output secondary to global effects of CPB and deep hypothermic circulatory arrest (DHCA). Left-lung hyperinflation on postoperative chest radiographs suggests compression of the left main stem bronchus. This complication tends to occur after difficult arch reconstructions when tension on the aorta causes it to press on the anterior surface of the bronchus, thus producing distal air trapping.

Hypoplastic Left Heart Syndrome

Pathophysiology

Among the congenital heart lesions, perhaps the most controversial has been management of HLHS. Left untreated, HLHS is a uniformly fatal disease; debate continues regarding the optimal management strategy (ie, staged palliation, neonatal transplantation, comfort care). In the current era, the 14-month transplant free survival ranges from 65% to 75%, making the comparative waitlist mortality for transplantation in these patients unacceptable. The results of surgical management vary among institutions and are clearly dependent upon expertise and experience,[157] the clinical condition of the neonate at presentation,[158] prematurity, multiple congenital anomalies, presence of an intact atrial septum, later age of presentation,[159] and degree of hypoplasia of left heart structures.[160,161]

This common example of single-ventricle physiology also represents the most severe form of obstructive left heart lesion. An anatomic spectrum of disease is implied for the lesion, but in its most severe and common presentation there is atresia or marked hypoplasia of the aortic and mitral valves with critical underdevelopment of the left atrium, left ventricle, and ascending aorta. A 1- or 2-mm ascending aorta gives rise to the coronary circulation and the head vessels before converging with the ductus arteriosus, where the aorta becomes larger and supplies the circulation to the lower body. Pulmonary venous return arrives in the diminutive left atrium and cannot cross the atretic mitral valve; therefore it is directed to the right atrium and right ventricle, where common mixing occurs with the systemic venous return and all blood is ejected into the pulmonary artery. Systemic blood flow is then supplied from the pulmonary artery, right-to-left, across the PDA. As the PDA constricts in the neonatal period, systemic blood flow decreases and all ventricular output is directed to the lungs. The Qp/Qs ratio approaches infinity as Qs nears zero. Therefore the paradoxical presentation of high PaO_2 (70-200 mm Hg) in the face of shock and profound metabolic acidosis is seen. When the ductus arteriosus is reopened with PGE_1, systemic perfusion is reestablished, the acidosis resolves, and the PaO_2 returns to the range of 40 to 60 mm Hg, representative of a Qp/Qs ratio between 1 and 2.

Critical Care Management

Adequate preoperative resuscitation with PGE_1 and correction of metabolic acidosis and end-organ dysfunction are crucial to the stabilization and management of patients with this lesion. Further facilitation of resuscitation can be enhanced by judicious use of inotropic agents, which can optimize cardiac output and end-organ perfusion. However, excessive delay in the timing of surgical intervention results in gradual reduction in PVR over days, with excessive pulmonary blood flow and inadequate systemic perfusion. The surgical reconstructive approach to this lesion now commonly entails three operations that ultimately aim to provide a 2- to 5-year-old child with a reconstructed aortic arch and a Fontan-type circulation for single-ventricle physiology.[162,163] In the first stage of the reconstruction (Norwood operation),[163] the pulmonary artery is transected at the bifurcation and an anastomosis is performed to the ascending aorta, which has been surgically incised so that the aortic and pulmonary arterial confluence arise together from the single

right ventricle as the neoaorta, which is extended into the remaining native aorta using homograft material. Pulmonary blood flow is established with either a modified BT shunt (usually 3.5 mm in diameter) or a RV-PA (Sano) conduit. The atrial septum is excised to ensure free flow of pulmonary venous return over to the TV. In addition to HLHS, the Norwood operation is used to repair other complex single-ventricle defects with systemic outflow obstruction or hypoplasia.[164]

The critical care considerations are the same as those outlined for patients with single-ventricle physiology. Perioperative management requires optimization of combined ventricular output, minimization of systemic oxygen consumption, and careful manipulation of Qp : Qs.

Postoperative Management

Evolution of Treatment Strategies.

Common teaching has held that postoperative mortality and hemodynamic lability are attributable to myocardial dysfunction and the physiologic burden imposed by a shunt-dependent pulmonary circulation in parallel with systemic blood flow. Treatment strategies have emphasized factors that may affect the balance between pulmonary and systemic blood flow. Immediately following a Norwood operation, PVR may be transiently elevated but soon decreases. Once PVR falls, treatment is aimed at raising resistance to blood flow through the lungs and redirecting cardiac output to the systemic circulation. High inspired concentration of oxygen, hyperventilation, alkalosis, systemic vasoconstriction, and anemia will cause further increase in pulmonary blood flow and should be avoided. Therapies designed to raise PVR and thereby direct aortic blood flow to the systemic circulation have focused on lowering the FiO_2 or allowing the $PaCO_2$ to rise with the pH falling toward 7.3. Further measures, such as ventilation with hypoxic gas mixtures or added carbon dioxide, have been advocated by some centers and have been intermittently embraced and abandoned by others. Validation of the effectiveness of these techniques to balance the pulmonary and systemic circulations has been difficult.[68,165]

The clinical focus on caring for the newborn following Norwood palliation for HLHS has evolved in stages since the 1990s. The early emphasis was on manipulating the PVR by optimizing mechanical ventilation (ie, mean airway pressure, tidal volume, rate and inspiratory time, FiO_2, and $PaCO_2$). It soon became apparent that the majority of this effort was aimed in the postoperative period to raise PVR and lower pulmonary blood flow while increasing systemic blood flow. Like any therapeutic strategy, manipulating gas exchange and inspired gases had its own set of adverse effects. High FiO_2 has well-defined pulmonary toxicity that may appear in a matter of days or even hours after exposure. Use of low FiO_2 (below room air concentrations) to raise PVR transiently and stabilize patients is both counterintuitive and a relatively uncommon therapy in clinical medicine. Whether iatrogenically induced or as part of a pathologic process, alveolar hypoxia can be life threatening when aggravated by unexpected hypoventilation. A mechanically ventilated and sedated patient on an FiO_2 less than 0.21 has little safety margin for dangerous hypoxemia even in the most intensively monitored environments. Excellent animal models of chronic pulmonary hypertension are produced by

relatively brief exposure to hypoxic gas. A newborn breathing hypoxic gas mixtures in the preoperative period of stabilization may have a favorable response by raising PVR and diminishing pulmonary blood flow. However, if this treatment is prolonged during preparation for reconstructive or transplantation surgery, the caretakers may be frustrated by subsequent elevation in PVR that persists during and after weaning from CPB.

In centers where neonates are allowed to awaken and breathe spontaneously during the immediate postoperative period, pulmonary blood flow may become excessive and further stimulate hyperventilation and respiratory alkalosis. Adding carbon dioxide to the inspired gas may reverse this trend toward respiratory alkalosis and stabilize the relative balance of the pulmonary and systemic circulations if the forces that drive minute ventilation are suppressed with agents for sedation or analgesia.[68,165] However, the metabolic cost of carbon dioxide breathing in an awakening child given little analgesia may discourage widespread application of this technique until the physiologic advantage over conventional means of controlling alveolar ventilation and $PaCO_2$ has been demonstrated. This is especially true in unsedated, preoperative patients where factors controlling respiration during carbon dioxide breathing may permit minimal change of $PaCO_2$ but substantially increase the respiratory rate and work of breathing.

The introduction of a 3.5-mm systemic-to-pulmonary shunt (rather than a 4-mm shunt) and the appreciation of the surgical complexity of an appropriately placed shunt did as much to reduce excessive pulmonary blood flow in infants as did manipulation of the ventilator. Although the smaller shunts were associated with a rare but real incidence of shunt thrombosis, those involved in postoperative care found patient management with a small shunt substantially easier than struggling with the tendency for pulmonary overcirculation with a 4-mm shunt. By the late 1980s it was apparent that this palliated circulation was required for only 10 to 12 weeks to reach an adequate patient size for the newly applied second stage of the procedure (bidirectional Glenn) to be performed. Therefore a relative increase in cyanosis (from a smaller shunt) was believed to be a justifiable price for more stable early postoperative hemodynamics. However, mortality rates did not plummet with the recognition of the advantage of smaller shunts and manipulating PVR, although by then many more centers were undertaking a staged reconstructive approach to HLHS. In the early 1990s attention was redirected to the observation that arterial oxygen saturation was only one variable in the assessment of Qp/Qs and that a perfectly acceptable arterial oxygen saturation of 80% in this disease may represent severe pulmonary overcirculation if the mixed venous oxygen saturation was only 20%. Hence a renewed interest in measuring and monitoring arterial and mixed venous oxygen saturations emerged. Thus in overcirculated patients with a small (3.5-mm) fixed-diameter shunt off of the subclavian artery, there was less emphasis on micromanagement of PVR and more interest in pharmacologically supporting cardiac output while reducing the systemic afterload to diminish the driving pressure across the shunt. Some have advocated use of the alpha-blocker phenoxybenzamine for blunting systemic vascular reactivity and dilating the peripheral circulation,[166] but its potent, long-lasting effects and associated hypotension that is not ameliorated by the usual alpha-agonist vasoactive agents can be challenging. The phosphodiesterase inhibitors then enjoyed a new and extensive application in pediatric critical care: lowering SVR, increasing cardiac output, and

lowering filling pressures. The new strategy was to monitor (arteriovenous) DO_2, support cardiac output, and reduce SVR.

Later in the decade, the observation of limited coronary reserve, low mixed venous oxygen saturation, rising lactate, and hemodynamic collapse in the first 48 hours helped emphasize the fundamental limitation of myocardial function and cardiac output in the early postoperative period. The morphologic RV and TV seem ill suited to support adequate systemic plus pulmonary blood flow. Several centers then embraced mechanical support of the circulation temporarily for the failing Norwood patient in the early postoperative period.

Specific Considerations for the Norwood Operation.

Management of patients following a Norwood-type operation is complex. Intensive monitoring is essential because the patient's clinical status can change abruptly with rapid deterioration. Persistent or progressive metabolic acidosis is a bad prognostic sign and must be aggressively managed. Considerations in the assessment of the circulation following the Norwood operation are given in Table 38.7.

TABLE 38.7

Management Considerations for Patients Following a Norwood Procedure

Scenario	Etiology	Management
SaO_2 ~80% SvO_2 ~60% Normotensive	Balanced flow ($Q_p = Q_s$)	No intervention
SaO_2 >90% Hypotension	**Overcirculated ($Q_p > Q_s$)** Low PVR Large BT shunt Residual arch obstruction	Raise PVR — Controlled hypoventilation — Low FiO_2 (0.17-0.19) — Add CO_2 (3%-5%) — Increase systemic perfusion — Afterload reduction, vasodilation — Inotropic support — Surgical shunt revision
SaO_2 <75% Hypertension	**Undercirculated ($Q_p < Q_s$)** High PVR Small, kinked, thrombosed BT shunt	Lower PVR — Controlled hyperventilation — Alkalosis — Sedation/paralysis Increase cardiac output — Inotropic support Hematocrit >40% Surgical intervention
SaO_2 <75% Hypotension Low SvO_2	Low cardiac output Ventricular failure Myocardial ischemia Residual arch obstruction Atrioventricular valve regurgitation	Minimize stress response Inotropic support Surgical revision Consider mechanical support Consider transplantation

BT, Blalock-Taussig; *FiO_2*, inspired oxygen concentration; *PVR*, pulmonary vascular resistance; *Q_p*, pulmonary blood flow; *Q_s*, systemic blood flow; *SaO_2*, arterial oxygen saturation; *SvO_2*, mixed venous oxygen saturation.

Ideally the pH should be 7.4, $PaCO_2$ 40 mm Hg, and PaO_2 40 mm Hg in room air, with a mixed venous O_2 saturation of 60% reflecting a well-balanced circulation. Higher saturations can be achieved if the systemic circulation is well dilated without compromising perfusion pressure. Frequent adjustments in mechanical ventilation settings and FiO_2 may be necessary in the first few hours after surgery. However, manipulations of FiO_2 in the face of a restrictive 3.5-mm shunt may have less impact

on pulmonary blood flow than would systemic vasodilation.[162] Leaving the sternum open after surgery may facilitate lower filling pressures, a balanced circulation, and a stable ventilation pattern.

Deep sedation or even muscle paralysis and anesthesia often are continued after surgery to minimize the stress response until the patient has a stable circulation and gas exchange. Inotropic support with dopamine and occasionally low doses of epinephrine usually are required, titrated to systemic pressure and perfusion. Afterload reduction with milrinone as a second-line agent is beneficial to reduce myocardial work and improve systemic perfusion. Monitoring SVC O_2 saturations, as a measure of mixed venous O_2 saturation (SvO_2) and cardiac output, is useful in this assessment. Volume replacement to maintain preload is essential, aiming for a common atrial pressure approximating 8 to 10 mm Hg.

The type, diameter, length, and position of the shunt affect the balance of pulmonary and systemic flow. Generally, a 3.5-mm modified BT shunt from the distal innominate artery provides adequate pulmonary blood flow without excessive steal from the systemic circulation for most full-term neonates. Nevertheless, a shunt resulting in a low diastolic pressure (<30 mm Hg) in turn affects perfusion to other vascular beds, particularly the coronary, cerebral, renal, and splanchnic perfusion. This may contribute to a prolonged and difficult postoperative course.

Overcirculation in the immediate postoperative period with an SaO_2 greater than 90% may reflect a low PVR or increased flow across the shunt if the shunt size is too large or the perfusion pressure is increased from residual aortic arch obstruction distal to the shunt insertion site. The increased volume load on the systemic ventricle results in congestive cardiac failure and progressive systemic hypoperfusion with cool extremities, oliguria, and metabolic acidosis. Although manipulation of mechanical ventilation and inspired oxygen concentration may help limit pulmonary blood flow, surgical revision to reduce the shunt size may be necessary.

If there is significant diastolic runoff through a large shunt, coronary perfusion will be reduced and lead to ischemia, low output, arrhythmias, and cardiac arrest. Rhythm disturbances are uncommon in the immediate postoperative period following a Norwood operation, and a sudden loss of sinus rhythm, particularly heart block or ventricular fibrillation, should increase the suspicion of myocardial ischemia and impending circulatory collapse.

In the immediate postoperative period, mild hypoxemia with a SaO_2 of 70% to 75% and PaO_2 of 30 to 35 mm Hg is preferable to an overcirculated state with high systemic oxygen saturations and falling mixed venous oxygen saturation. Pulmonary blood flow often increases on the first postoperative day as ventricular function improves and PVR falls during recovery from CPB. Pulmonary venous desaturation from parenchymal lung disease such as atelectasis, pleural effusions, and pneumothorax requires aggressive management.

Persistent desaturation and hypotension reflects a low cardiac output from poor ventricular function, thereby decreasing the perfusion pressure across the shunt. SvO_2 is low (often <40%), and treatment is directed first at augmenting contractility with inotropic agents and subsequently reducing afterload with a vasodilator. This is a serious clinical problem with a high mortality after a Norwood operation. The related myocardial ischemia and acidosis further impair myocardial function and systemic perfusion, leading to circulatory collapse.

Atrioventricular valve regurgitation and residual aortic arch obstruction are important causes of persistent low cardiac output and inability to wean from mechanical ventilation. Echocardiography is useful for assessing valve and ventricular function but is less accurate for assessing the degree of residual arch obstruction. Cardiac catheterization is sometimes necessary and will enable fine-tuning of hemodynamic support or balloon dilation of a hypoplastic segment of narrowed aorta. Occasionally, surgical revision of the aortic arch or atrioventricular valve is necessary, although this is seen more commonly in the interval before the bidirectional cavopulmonary shunt.

The advocated Sano modification of the Norwood procedure involves placement of a conduit from the right ventricle to the PA confluence (RV-PA shunt).[167,168] The primary advantage of this procedure in the immediate postoperative period is improved diastolic perfusion without runoff across an aortopulmonary shunt. Ventricular function is less likely to be compromised after surgery because the volume load to the ventricle is reduced from a lower Qp/Qs, along with a reduced risk for myocardial ischemia because of improved coronary perfusion. Perfusion to cerebral, renal, and splanchnic circulations also is likely to be improved with the lack of diastolic runoff to the pulmonary circulation, which may enhance postoperative recovery. Because pulmonary blood flow occurs only during ventricular systole across the right ventricle to the pulmonary artery conduit, there may be a critical reduction in pulmonary blood flow and excessive hypoxemia, especially during periods of low cardiac output or if there is dynamic obstruction to flow at the ventricular insertion site. Efforts to overcome this limitation by creating a larger RV incision run the longer-term risk of ventricular dysfunction, arrhythmias, or aneurysm formation.

A multicenter, randomized, controlled trial involving 549 neonates with HLHS demonstrated a significantly improved transplantation-free survival for patients randomized to receive a RV-PA shunt compared to those palliated with a modified BT shunt (74% versus 64%, $P = 0.01$).[169] The major benefit of the RV-PA shunt seems to be an increased survival rate in the early period after the procedure. The short-term survival advantage of the Sano modification of the Norwood operation for centers where mortality rate after the Norwood operation already was below 15% will be hard to demonstrate. More recent long-term follow-up, however, demonstrates an elimination of this survival advantage at 3 years of age with the RV-PA shunt group.[170] In addition, this group had worse RV ejection fraction validating concerns regarding the impact of an incision in the systemic ventricle.[170]

Orthotopic heart transplantation has gained acceptance as an alternative treatment for HLHS.[171] Neonatal transplants appear to be well tolerated, and some centers have avoided maintenance steroid therapy while achieving excellent midterm results using transplantation as the sole therapeutic option for this disease.[172,173] Others have successfully advocated a combined approach using either transplantation or staged reconstruction, depending on the pathophysiologic state of the child and the availability of a donor heart. However, the critical shortage of donor organs places a marked limitation on correction of this common congenital heart lesion.

It is apparent that many children have derived benefit from a completed, staged reconstruction or heart transplantation for this previously fatal illness. They are often able to lead active, productive lives, and many do develop normally.[174,175] Both survival and developmental outcomes for this disease are improving worldwide.

However, the long-term prognosis for this evolving therapy will not be known for several years.

Hybrid Approach.

An innovative alternative to the stage I Norwood palliation that eliminates the insult associated with CPB in the fragile neonate with HLHS has been developed. This approach combines interventional cardiac catheterization techniques with less involving surgery and is referred to as the hybrid procedure.[176,177] The goal is to replicate the physiologic state of the Norwood procedure by the combination of three interventions: (1) placement of bilateral pulmonary artery bands to limit flow to the lungs, (2) placement of an endovascular stent to maintain the long-term patency of the ductus arteriosus, and (3) balloon atrial septostomy with or without stenting of the atrial communication to ensure adequate mixing and unrestricted left-to-right atrial flow.[176-179] This is accomplished through a standard medial sternotomy and does not require CPB.

The procedure requires superb coordination between the surgical and cardiac catheterization teams. It is generally performed in a hybrid suite consisting of a large modern cardiac catheterization laboratory with enough room to accommodate the surgeons and supporting operating room staff, in addition to the interventional cardiology team and anesthesiologists. Outcomes have been encouraging with early mortality comparable with that of standard protocols (about 15%-20%).[180,181] Direct comparison of the two methods is complicated because, in most centers, the hybrid procedure generally has been reserved for patients regarded as high risk for bypass surgery (eg, low birth weight, unstable hemodynamics, and poor ventricular function). Interstage mortality can be significant (15%-20%),[180] and case-matched studies have shown no benefit over conventional surgery.[179] One barrier to the widespread implementation of the hybrid procedure is that results of conventional surgery in the low-risk groups are now so good that many centers of excellence have been reluctant to undertake a new procedure with its attendant learning curve.

The hybrid procedure poses some unique technical challenges: The ductal stent position is crucial and, if patients have a diminutive ascending and transverse aorta, then the procedure does not address this impediment to coronary flow. If the transverse aorta is small, the stent itself might distort or interfere with retrograde flow into the arch, and for this reason most centers do not recommend the hybrid approach in the setting of a small transverse arch. Nevertheless, the hybrid approach undoubtedly has a role in the management of patients with HLHS and, with continued encouraging results[182] beyond the centers of excellence that developed and advanced this technique, it has found a niche among high-risk patients or as a bridge to transplantation.

Up to 50% of patients that survive the stage I hybrid procedure require catheter reintervention due to stent migration or restrictive flow across the atrial communication.[180] The stage II procedure becomes much more extensive than the conventional stage II because the aortic arch needs to be reconstructed (excising the ductal stent), the bands removed, and the pulmonary arteries repaired with a patch in addition to creating the cavopulmonary connection. Consequently, the stage II after the hybrid procedure carries higher operative mortality (10% to 15%), and this needs to be taken into account when comparing it with conventional techniques.[180,182] No absolute consensus exists on the future of the hybrid procedure. This innovative

approach offers potential benefits that should be scrutinized through careful study and long-term follow-up.

Summary

The cardiac ICU has become the epicenter of activity in large cardiovascular programs. Nowhere are collaborative practices and multidisciplinary skills more valued or necessary. A curriculum in cardiac intensive care is now formally incorporated into cardiology training. Pediatric intensive care training programs have a mandate to include curricula and experience in the management of postoperative cardiac patients. Additional cardiac intensive care training is offered in selected centers to pediatric intensive care specialists wishing to pursue a career in the cardiac intensive care unit. Specialists in this field must have in-depth training in pediatric intensive care and cardiology as the scope of practice goes well beyond the cardiovascular system and requires expertise in complex respiratory physiology, diagnosis and management of multiorgan system dysfunction, and the various supportive techniques vital to the discipline of intensive care, to name a few. Increased complexity of disease, advances in technology and applied research, shortened lengths of stay, and improved survival in contemporary series (Table 38.8) all describe the fast-paced specialized environment that has accompanied the development of this new specialty of pediatric cardiac intensive care. Although the dramatic reduction in mortality has been gratifying in cardiac intensive care and is attributable to many factors, achieving 100% survival with minimal morbidity remains our elusive goal. It will challenge the next generation of practitioners.

TABLE 38.8

Contemporary Outcomes for Benchmark Operations (January 2011 to December 2014)

Procedure (Diagnosis)	Number of Operations	Operative Mortality Rate
Coarctation (off bypass)	3947	1.0%
Ventricular septal defect (VSD)	6985	0.7%
Tetralogy of Fallot	4519	1.0%
Atrioventricular canal defect	3116	3.2%
Arterial switch	1851	2.7%
Arterial switch + VSD	798	5.3%
Glenn/hemi-Fontan	3946	2.1%
Fontan	4164	1.4%
Truncus arteriosus	614	9.6%
Norwood (stage I palliation)	2828	15.6%

CHAPTER 39

Cardiac Transplantation

F. Jay Fricker

PEARLS

- Indications for transplantation are cardiomyopathy and complex palliated congenital heart disease with severe myopathic ventricular dysfunction.
- Pediatric patients on inotropic support or circulatory support and who have life-threatening arrhythmia receive priority for available pediatric donors.
- Selection of the agent to initiate inotropic support has evolved from sympathomimetic agents (dobutamine/dopamine) to the phosphodiesterase inhibitor milrinone.
- Virtual cross-match is now used in sensitized patients to improve organ allocation.
- It is imperative that immune suppression be initiated immediately after heart transplantation.
- The high-risk period for acute allograft rejection is in the first month after transplantation.
- Complications of immune suppression are infection, acute renal failure, malignancy, and hyperglycemia.

It has now been a quarter of a century since the first successful pediatric heart transplant was performed at Stanford University.[1] The introduction of cyclosporine as the primary immune suppressant agent used in solid organ transplantation was a key discovery because it was the first selective immunosuppressive agent used in solid organ transplant recipients. It has spared corticosteroid use and has made heart transplantation a cost-effective procedure.[2] In the past 25 years, perioperative mortality has become negligible even in patients with the most complex congenital heart defects. Advances have occurred in our understanding of the immune system, and improvement in critical care management of both donor and recipient patients has resulted in an increased survival benefit. This chapter reviews critical care management of the pediatric patient with cardiopulmonary failure who is evaluated for orthotopic heart transplantation. Donor management, physiology of the transplanted heart, and preoperative and perioperative critical care all play important roles in the successful outcome of critically ill children with no option other than heart replacement surgery.

Indications for transplantation are cardiomyopathy and complex palliated congenital heart disease with severe myopathic ventricular dysfunction.[3] The Pediatric Heart Transplant Study Group reviewed the causes of death after heart transplantation from a prospective database initiated in 1993. Patients were entered into the database on an intention-to-treat basis.[4-6] Using parametric data analysis with competing outcomes, death while waiting for transplant has been analyzed for all age groups, pretransplant diagnosis, blood type, and urgency status. Early death after heart transplant has been categorized as primary heart allograft failure. This includes inadequate preservation from long ischemic time and primary right ventricular failure from high pulmonary vascular resistance (PVR). Acute allograft rejection is an exceedingly rare event immediately after implantation. Late death after transplant is the result of posttransplant coronary vasculopathy, malignancy, or nonadherence to immune suppression regimens.[7,8]

The technical complexities of heart transplantation in children with palliated congenital heart disease contributed to the early perioperative mortality, which exceeded 30%. In addition, difficulties in estimating PVR, variable pulmonary artery anatomy, and complications from multiple repeat thoracotomy and sternotomy all contributed to early morbidity and mortality.[9] Solid organ preservation, surgical experience, and recipient selection have all improved with experience, resulting in reduced perioperative mortality that is equivalent to transplantation of the primary cardiomyopathic patient who has not had a previous sternotomy.[9,10] Primary transplantation in the neonate with hypoplastic left heart syndrome (HLHS) has caused controversy because an acceptable surgical alternative is available and infant donor heart resources are limited.[11] In reviews from the Pediatric Heart Transplant Study Group Database, the mortality of infants waiting for donor heart availability exceeds 25%.[4] In recent years, deaths while waiting for transplantation have decreased, but this decrease reflects the smaller number of infants listed and those who have opted for the Norwood procedure and single-ventricle palliation. The Norwood procedure does not preclude the possibility of future transplantation.

Late death after heart transplantation is related to either accelerated allograft coronary artery disease or primary malignancy.[12,13] The major cause of death in the adolescent heart transplant recipient is now noncompliance with the medical regimen.[7] With the decrease in perioperative mortality, we now expect 5-year survival after heart transplantation to exceed 80%. From the newest survival data (International Society for Heart and Lung Transplantation 2009 Report), the transplant half-life (the time at which 50% of the recipients remain alive) is 11.3 years for teens and 15.8 years for infants.[14] Rehospitalization after the first year is rare, and quality of life has been excellent.[15]

Critical Care of the Pediatric Patient Waiting for Heart Transplantation

The number of good donor hearts available to satisfy the number of potential adult recipients is not adequate. Statistics from the United Network for Organ Sharing (UNOS) demonstrate this discrepancy between the number of potential recipients for heart and lung transplants and the availability of potential donors.[16] Donor availability for the pediatric patient is not as critical. Pediatric patients usually

receive an appropriate donor offer unless they are infants or are adolescents of a size such that they are competing with critically ill adult patients. Guidelines from UNOS regarding organ distribution have changed to ensure that pediatric adolescent donors are available first to potential adolescent and young adult pediatric recipients for both heart and lungs.

For potential heart transplant recipients, urgency criteria have been established for the most critically ill patients. Pediatric patients on inotropic support or circulatory support or who have life-threatening arrhythmia receive priority for available donors (Box 39.1).

Box 39.1

Heart Transplantation Justification

Pediatric Cardiology Status IA

- Requires assistance with a ventilator
- Requires assistance with a mechanical assist device (eg, extracorporeal membrane oxygenation, left ventricular assist device)
- Requires assistance with an intra-aortic balloon pump
- Patient younger than 6 months with congenital or acquired heart disease exhibiting reactive pulmonary hypertension >50% of systemic blood pressure levels
- Requires infusion of a single high-dose inotrope (eg, dobutamine ≥7.5 μg/kg/min or milrinone ≥0.5 μg/kg/min)
- Patient does not meet any of the criteria specified above but has a life expectancy without a heart transplant of <14 days (ie, refractory arrhythmia)

Management of the Potential Heart Transplant Recipient

The pretransplant management of the critically ill patient with end-stage myocardial dysfunction can determine the outcome of that patient after thoracic transplant. The principles of inotropic support, preservation of end-organ function, and attention to issues of nutrition and infection are the same for all critically ill patients in the pediatric ICU.

Evaluation of the potential heart transplant recipient requires a careful pretransplant hemodynamic assessment. This information can guide the fluid and inotropic therapy by optimizing preload and afterload while waiting for organ availability. The critical hemodynamic information influencing the function of the donor heart is an assessment of pulmonary artery pressure and PVR in the recipient before implantation. High PVR is associated with an increased perioperative transplant mortality rate and adverse long-term outcome.[17,18] A transpulmonary gradient greater than 15 mm Hg (mean pulmonary arterial pressure minus mean left atrial pressure) is associated with a higher incidence of heart graft dysfunction.[18]

Preoperative hemodynamic assessment should include measurement of both left and right heart pressures with interventions to manipulate the PVR if elevated. Remeasuring hemodynamics with FiO_2 of 1, nitric oxide, prostacyclin, and aggressive vasodilator therapy to decrease systemic vascular resistance (SVR) can help determine whether the patient is a heart transplant candidate or if he or she should be considered for lung or heart and lung transplantation.[19,20]

Inotropic Support

Critically ill children with myopathic ventricular dysfunction severe enough for them to be in the ICU are on inotropic support. These agents increase contractility through a common pathway of increasing intracellular levels of cyclic adenylate monophosphate (cAMP). Increased cytoplasmic levels of cAMP cause increased release of calcium from the sarcoplasmic reticulum and increase contractile force generation. Increases in cAMP occur either by β-adrenergic–mediated stimulation (increase in production) or phosphodiesterase III (PDE III) inhibition (decreased degradation). Milrinone has proven to be a well-tolerated agent. IV administration of milrinone increases cardiac output and reduces cardiac filling pressures, PVR, and SVR, with minimal effect on heart rate. Milrinone has been well studied in the pediatric population, and the benefit is primarily related to effect on SVR and PVR rather than inotropy.[21,22] Milrinone is initiated at doses of 0.25 μg/kg/min and increased to 1 μg/kg/min without adverse effects. Although atrial and ventricular ectopy are less common with milrinone than dobutamine, ventricular ectopy/ventricular tachycardia can occur with the initiation of milrinone therapy. Tachyphylaxis is unusual with this agent. Milrinone has a long half-life and should be used cautiously in patients with hypotension. This drug is primarily excreted in the urine, so concentrations can increase in the presence of renal failure. We have observed severe hypotension and renal dysfunction precipitated by use of an angiotensin-converting enzyme inhibitor in a patient already on milrinone infusion. The addition of low-dose dobutamine (5–10 μg/kg/min) or epinephrine (dose 0.01–0.05 μg/kg/min) can help stabilize the critically ill child who is not responding adequately to milrinone therapy alone.

Nesiritide, a recombinant B-type natriuretic peptide, is now approved for treatment of acutely decompensated heart failure. Endogenous B-type natriuretic peptide is a cardiac hormone produced by the failing heart, and nesiritide is identical to the naturally occurring peptide. Nesiritide reduces preload and afterload, leading to increases in cardiac output/index without reflex tachycardia or direct inotropic effect. In addition, this drug promotes natriuresis and diuresis and suppresses the renin-angiotensin axis and endogenous catecholamines. Although this drug has not been studied extensively in the pediatric age group, in our and others' experiences, it has been found to be a safe and effective adjunctive therapy.[23,24]

Mechanical Support

Most patients waiting for transplantation who are on inotropic support do not remain hemodynamically stable indefinitely. Progressive end-organ dysfunction ensues, requiring escalation of support that includes multiple inotropic agents, in addition to respiratory and circulatory support. Mechanical circulatory support has

become an important addition to the treatment armamentarium for the infant or child with decompensated heart failure and low cardiac output unresponsive to pharmacologic maneuvers.[25] Options include extracorporeal membrane oxygenation (ECMO), intra-aortic balloon, and left and right ventricular assist devices. Experience with ECMO as a bridge to heart transplantation has been reported by several pediatric transplant centers.[26,27] ECMO support can be used for 2 to 3 weeks without major complications from bleeding or infection, extending the window for donor organ availability. Isolated ventricular support devices, such as the Thoratec, Berlin Heart,[28] and DeBakey centrifugal pump, are now available for children.[29,30] The Berlin Heart EXCOR has become the primary extracorporeal circulatory device in infants and children. The current data from Berlin Heart show there have been a total of 698 patients supported for more than 47,000 days with this pneumatic-driven device (personal communication, Berlin Heart). The longest time of support in an individual patient was 902 days, with an average of 68 days of support before transplantation, explant, or death. The pediatric demography is that this device is used for all pediatric age ranges, but the mean age of 5 years and the median age of 2 years reflect the benefit in small children because of the availability of a pump size that can deliver 10-mL stroke volume. Actuarial survival of patients at 1 year who have been bridged to heart transplant or explanted now exceeds 80% (personal communication, Berlin Heart). In the past, use of these devices had always been considered extraordinary and usually proposed in patients with severe end-organ dysfunction. Placement of a device in a patient with multisystem organ failure usually results in a poor outcome. We propose that these devices be placed early, before end-organ dysfunction; doing so will enable rehabilitation of the patient, who then becomes a more optimal candidate for organ transplantation.

Anticoagulation

All patients with severe myocardial dysfunction are at risk for complications of systemic and pulmonary embolus. In our experience, nearly all explanted hearts have mural thrombi in both the left and right ventricles. Pulmonary emboli lead to increased PVR and the potential for lung abscess. The most devastating result of systemic embolus is stroke. All patients waiting for transplantation should be managed with systemic anticoagulation. Heparin is preferred, but warfarin is acceptable in a stable patient on inotropic support. We add a word of caution regarding the use of low-molecular-weight heparin for prophylaxis. Enoxaparin cannot be easily reversed in a patient who must go to the operating room emergently because a donor heart has been identified. Cardiovascular surgeons prefer using heparin for prophylactic anticoagulation.

Management of the Potential Heart Donor

Many potential heart donors are lost because of suboptimal management after brain death has occurred. Associated with brain death is a catecholamine surge causing unnatural circulatory physiology that rapidly evolves, making management of the donor difficult. This intense sympathomimetic outflow initially causes vasoconstriction resulting in tachycardia, hypertension, and increased myocardial oxygen demand. The result can be a direct injury to the myocardium in the

potentially transplantable heart. Myocardial structural damage is seen and includes myocytolysis, contraction band necrosis, subendocardial hemorrhage, edema formation, and interstitial mononuclear infiltration.[31] This initial sympathetic outflow is followed by a loss of sympathetic tone resulting in marked vasodilatation and hypotension. The hypotension and cardiovascular collapse are related to decreased SVR rather than primary myocardial dysfunction. Large fluid volumes and high-dose inotropic agents at α-adrenergic dosing range are administered, causing volume overload and vasoconstriction that can injure all donor organs. Hearts that are supported on high-dose inotropic agents will likely exhibit myocardial injury. A risk factor that predicts donor heart failure is a history of use of high-dose dopamine, dobutamine greater than 20 μg/kg/min, and epinephrine greater than 0.1 μg/kg/min.

Hormonal changes occur with brain stem injury and death. Early depletion of antidiuretic hormone causes inappropriate diuresis. Depletion of free triiodothyronine (T_3) has been implicated in myocardial dysfunction. Falling insulin levels lead to decreased intracellular glucose levels. A significant decrease in cortisol levels contributes to cardiovascular instability.[32,33]

Our present understanding of the physiology of brain death has resulted in "protocol" development for management of the potential donor. The principles of support include the following:

- Invasive cardiovascular monitoring maintaining a mean arterial blood pressure greater than 60 mm Hg and central venous pressure of 6 to 10 mm Hg.
- Vasopressin is now the first-line blood pressure support medication because it treats diabetes insipidus in addition to supporting blood pressure. Infusion of less than 2.5 U/hour is usually sufficient to increase mean arterial blood pressure and not cause end-organ injury.
- Respiratory support to maximize oxygen delivery to transplantable organs. Recommended ventilatory strategies are aimed at optimizing oxygenation and preventing lung injury.
- Hormonal support including high-dose corticosteroids in the form of Solu-Medrol, insulin, and, possibly, infusions of the thyroid hormone T_3 or T_4. The benefits of thyroid hormone replacement in the brain-dead donor are debated, but there are studies supporting their use.[32] Resuscitation of the "marginal donor heart" is worth the effort, given the shortage of available donor organs. Administration of T_3 has been advocated for reversal of myocardial dysfunction induced by the catecholamine surge of brain death.[32]

Pediatric heart transplantation after declaration of cardiocirculatory death has received significant interest in the transplant community because of the shortage of donor organs. Protocols are controversial because donor care is provided under the direction of the pediatric intensivists. The donor is moved to the operating room, and femoral arterial and venous lines are inserted for access to perform organ resuscitation. The donor is given comfort care, extubation is accomplished, and the donor is monitored for circulatory death by auscultation of the heart and palpation of pulses. When circulatory death has occurred, the donor is observed for a period of 1.25 to 3 minutes before death is declared. If cardiocirculatory death occurs within 30 minutes after extubation, the donor is declared a candidate for organ donation. Cold

cardioplegia is infused into the catheter that was positioned in the ascending aorta, sternotomy is performed, and topical cooling of the heart is initiated. The inferior vena cava is opened to prevent distension of the heart. The routine technique for cardiectomy is then performed.[34] Organ donation after circulatory death for kidney and liver transplantation is becoming more common, but because the heart is more vulnerable to ischemia, this practice has not become common. The practice of transplantation after cardiocirculatory death for any organ remains an ethically controversial practice for many pediatric critical care intensivists.[35]

Critical Care Management of the Orthotopic Heart Transplant Recipient

Intraoperative Considerations

Heart replacement can be accomplished in virtually any congenital heart anomaly because the aorta, pulmonary arteries, and left atrium are in a relatively constant position near the midline. Regardless of malposition or positional relationships of the great arteries, the aorta of the recipient can be mobilized to make anastomosis with the donor aorta possible. The left atrium is a midline structure, and even when anomalies of the pulmonary venous return exist, pulmonary veins usually approach the midline and can be incorporated into the repair.[36]

Techniques of implantation have not changed significantly since the original description.[1,37] The newest innovation is the bicaval anastomosis.[38,39] This technique has the advantage of preserving sinus node function.[40] Implantation techniques require that the pulmonary veins come to the midline. The pulmonary artery and aorta can be malpositioned, but this adds little to the technical difficulty of the procedure. Aortic root size mismatch can, however, cause technical difficulty. Implantation of recipients with complex congenital heart disease can usually be accomplished by harvesting additional donor pulmonary artery, aorta, and caval tissue to replace deficient recipient tissue or to correct malposition of the vena cava or great arteries.[36,41]

Donor heart function is related to proper management of the donor and the total ischemic time of the donor heart. The amount of time the aorta is cross-clamped on the donor until the aortic anastomosis is completed on the recipient (total ischemic time) is a major factor determining early postoperative donor heart function. Nevertheless, donor hearts have been exposed to more than 8 hours of ischemia and recovered function after transplantation.

Early Perioperative Management

The early perioperative management of the recipient is not significantly different from the management of any postcardiac surgical patient. The physiologic responses of the newly transplanted heart are altered because of denervation. The major changes related to autonomic denervation include diastolic dysfunction and exaggerated response to exogenously administered catecholamines. The transplanted heart must also adapt to a new environment related to recipient lung function and elevated PVR.

Autonomic system denervation results in a relatively fixed heart rate without

respiratory variation. Heart rates are between 90 and 110 bpm but can be faster because of exogenous catecholamine administration. (The sinus node is transplanted with the donor heart.) Heart rates can be slower if the recipient has been exposed to amiodarone pretransplant or if there was injury to the blood supply of the donor sinus node at the time of donor heart removal.

Early blood pressure instability is common because of loss of baroreceptor regulation and dependence of the transplanted heart on endogenous or exogenous catecholamines. Hypertension occurs because of a fixed stroke volume into a systemic vascular bed that is abnormal because of long-standing increase in systemic vascular resistance from compensatory heart failure. Size mismatch between donor and recipient can also contribute to the hypertension because of a large stroke volume from the transplanted heart. The other concern about donor heart/recipient mismatch is "big heart," or hyperperfusion syndrome. A well-functioning large allograft generates a large stroke volume causing systemic hypertension and high cardiac output in a patient who previously had a low cardiac output state. This increase in cerebral blood flow has the potential to cause cerebral vasoconstriction and symptomatic seizures, headache, or changes in mental status.[42] These symptoms are limited to the first few days after transplantation. There is a gradual adaptation in allograft stroke volume to the needs of the recipient. This adaptation of oversized cardiac allografts in children is part of the "shrink and grow" phenomenon previously described.[42] The oversized donor heart eventually undergoes remodeling with regression of hypertrophy. Although this is a rare problem in children, symptomatic hypertension must be treated aggressively early in the perioperative period.

Early myocardial function of the transplanted heart is dependent on catecholamine support. Small infusions of β-adrenergic agents such as isoproterenol for several days are often necessary to maintain optimal heart allograft function.[43]

The hemodynamics of the transplanted heart reflect a significant shift to the left of the pressure/volume curve. Diastolic dysfunction can be demonstrated from the early transplant period. Why this hemodynamic abnormality is present early because of preservation injury is understandable, but diastolic dysfunction persists well into the recovery phase and beyond. Fluid administration of 10 mL/kg to a heart transplant recipient months remote from transplant will uncover an occult restrictive hemodynamic pattern. Pulmonary artery wedge pressure will increase by twofold, and right atrial pressure will increase more than expected.[44] In the normal heart, right atrial pressure will not change and left atrial pressure will increase by 1 to 2 mm Hg in response to a fluid challenge.

Diastolic dysfunction is a significant impairment to early allograft function, limiting cardiac output. Diastolic dysfunction emphasizes the importance of heart rate and early sinus node function. The capability for temporary pacing in the early perioperative period is mandatory.

Management of Early Heart Allograft Dysfunction

Early heart allograft dysfunction is related to primary failure of the heart allograft because of unsuspected injury to the heart prior to procurement or because of preservation injury. The other major cause of primary allograft failure is elevated PVR in the recipient. Allograft failure is rarely caused by acute antibody-mediated

injury. Risk factors associated with donor heart dysfunction, if present, should be factored into the decision of accepting that particular heart for your patient. Obviously the condition of the recipient and the expected length of survival would mandate, at least, consideration for acceptance of a "marginal heart."

Risk factors for donor heart dysfunction include "down time of the donor" (length of initial resuscitation), evidence of myocardial injury with elevation of troponin I, and a history of high-dose inotropic support (dopamine/dobutamine >20 μg/kg/min or epinephrine/norepinephrine >0.1 μg/kg/min) in the donor. Objective assessment of donor heart function can be made by obtaining an echocardiogram and electrocardiogram. The echocardiogram assesses donor heart systolic function (shortening fraction or left ventricular ejection fraction) and will detect the presence of mitral valve regurgitation or wall-motion abnormalities. The presence of any of these abnormalities makes the donor heart "marginal" for transplantation. In assessing the donor heart function, serial echocardiograms are imperative before determining that the heart is not usable for transplantation. Abnormal heart function seen in the midst of the catecholamine storm of brain death can recover. Repeating the echocardiogram remote from the initial resuscitation period or after the reduction or discontinuation of inotropic support can increase one's confidence in accepting the donor heart.

The other major reason for primary donor heart dysfunction is right heart failure from high PVR. We have known since the early days of heart transplantation that the donor right ventricle will not function when exposed to an abnormal pulmonary circulation. High PVR in the recipient increases perioperative morbidity and mortality and can affect late survival. All potential heart recipients undergo cardiac catheterization before heart transplantation to document the anatomy of systemic and pulmonary venous connections, determine pulmonary artery size and distribution, and calculate PVR. The upper limit of PVR associated with successful orthotopic heart transplantation is not known. Criteria developed from the adult heart transplant experience indicate that a PVR greater than 6 Wood units or a transpulmonary gradient (pulmonary artery mean pressure minus left atrial mean pressure) greater than 15 mm Hg is associated with increased perioperative mortality. The transpulmonary gradient is the most useful number for estimating PVR because measurement of cardiac output in the catheterization laboratory can be flawed. In children, PVR index (PVRI), determined by dividing transpulmonary gradient by cardiac index, is more useful, because children come in all sizes. PVRI less than 6 index units is associated with low perioperative mortality. Orthotopic heart transplants have been successful with PVRI greater than 6 and as high as 10 index units, but with increased morbidity and mortality rates. The diagnosis of high PVR is evident as the patient is weaned from cardiopulmonary bypass. Intraoperative transesophageal echocardiography demonstrates dilatation of the right ventricle and a small, underfilled left heart. Acute management of high PVR and right heart dysfunction includes high FiO_2 and administration of nitric oxide at 20 to 40 ppm. The need for continuous pulmonary vasodilator medications in the immediate perioperative period is unusual, but prostacyclin and sildenafil have both proved effective in this situation.[45]

The sinus node artery from the donor heart is at risk at the time of procurement, and the incidence of sinus node dysfunction causing junctional rhythm or atrial flutter/fibrillation is 10% to 20%. Nearly 5% of children require pacemaker therapy

after transplantation because of sinus node dysfunction.[46] All transplant recipients have temporary pacing wires, so bradyarrhythmias are not an issue. If the patient is in atrial flutter/fibrillation, then cardioversion should be performed. Persistent sinus node dysfunction with bradycardia can be problematic because of early diastolic dysfunction of the heart allograft. In the usual scenario, the patient returns from the operating room in an atrial paced rhythm. When the pacemaker is turned off, the underlying rhythm is a junctional rate between 100 and 120 beats/min. As inotropic support is discontinued, the junctional rate slows to an unacceptable rate in the 50 to 80 beats/min range. Usually an occasional atrial contraction is conducted, but the sinus node has been injured. Initiating theophylline at a dose of 10 mg/kg/day is helpful. Permanent pacing is recommended if sinus or atrial conducted rhythm has not returned within 2 weeks.

Heart Allograft Rejection and Immune Suppression

It is imperative that immune suppression be initiated early after heart transplantation. Solid organ transplants transfer antigen-presenting cells (APCs) that are recognized by the recipient's human leukocyte antigen (HLA) immune system as foreign, which sets up a cascade of lymphocyte stimulation and proliferation. These lymphocytes then migrate to the heart allograft, where they can adhere to myocytes and endothelial receptors and cause tissue destruction. T-cell activation is the prime mover of allograft rejection. The initial signal is T-cell receptor binding of antigen on the surface of an APC. The APC is derived from the donor in the form of a monocyte, or a tissue macrophage. Interaction of the APC and T-cell receptor causes release of interleukin (IL)-1 from the APC, which causes activation of the T cell. Activated T cells secrete IL-2 and other lymphokines that induce proliferation of activated T cells, which migrate to the allograft causing tissue damage.

Initial immune suppression protocols include high-dose corticosteroids, induction with IL-2 receptor blockade, or antithymocyte globulin, followed by introduction of the calcineurin inhibitors cyclosporine or tacrolimus (Table 39.1).

TABLE 39.1

Immune Suppression in the Intensive Care Unit

Agent	Mechanism of Action	Dose	Monitoring	Major Side Effect(s)
Induction Immune Suppression				
Corticosteroids	Redistribution of peripheral lymphocytes, inhibition of lymphokine IL-2 production, impairment of macrophage response to lymphocyte signals	Induction Immune Suppression Corticosteroids Dose 10 mg/kg every 8 hours times 3 doses 5 mg/kg every 8 hours times 3 doses 1 mg/kg every 8 hours times three doses 1 mg/kg/day tapering to 0.5 mg/kg at Hospital Discharge	Glucose	Infection, cushingoid appearance, hypertension, hyperlipidemia, glucose intolerance
Basiliximab	Monoclonal antibody binds to IL-2 receptor	20 mg >35 kg 10 mg <35 kg, administer days 1 and 4	CBC	Anaphylaxis
Antithymocyte globulin	Nonspecific T-cell lysis	Antithymocyte Globulin Dose 1 mg–1.5 mg/kg/day for 3–5 days Note: We are trying to decrease the total dose of ATG	T-lymphocyte subsets	Thrombocytopenia, anaphylaxis, infection, PTLD, localized pain with RATG administration,

				serum sickness
Cyclosporine	Calcineurin inhibitor, inhibition of T-cell receptor lymphokine production and T-cell proliferation	2.5 mg/kg/24 h IV	Monoclonal whole blood assay 100–400 ng/mL, depending on time since transplantation	Nephrotoxicity, central nervous system seizures, decreased magnesium, hypertension, hirsutism, gingival hyperplasia
Tacrolimus	Calcineurin inhibitor, inhibition of T-cell receptor lymphokine production and T-cell proliferation	Pretransplant 1.0 mg (given 4–8 hours before going to OR for transplant) IV: 0.03–0.05 mg/kg/24 hours Note: We avoid the use of tacrolimus IV because of high risk of renal failure; therefore do not recommend using this drug intravenously early after transplant Oral: 0.5–1.0 mg (or 0.1–0.3 mg/kg) twice daily and increase the dose to therapeutic level 10–15 ng/mL after transplant	10–15 ng/mL, whole blood	Nephrotoxicity, anemia/neutropenia, headache, tremors, insomnia, glucose intolerance
Maintenance Immune Suppression				
Cyclosporine		5–20 mg/kg 2× or 3× daily		
Tacrolimus		0.3 mg/kg/day divided 2× daily		
Sirolimus	Inhibition of T-cell activation and proliferation by preventing translation of mRNA		Triglycerides, platelets 5–10 mg/mL	Nephrotoxicity, hyperlipidemia, thrombocytopenia, leukopenia, gastrointestinal intolerance
Azathioprine	Antimetabolite inhibits purine and DNA synthesis	1–2 mg/kg/day	WBC <4000 ANC >1500	Bone marrow suppression
Mycophenolate mofetil		Mycophenolate mofetil or mycophenolic acid 30–60 mg/kg/day or 600 mg/m^2/day	WBC <4000 ANC >1500	Bone marrow suppression, gastrointestinal intolerance
Prednisone		1–3 mg/kg/day		
Acute Cellular Rejection				
Methylprednisolone				
Antithymocyte globulin		1.5 mg/kg/day for 7–14 days		Peripheral lymphocyte count, platelet count

ANC, absolute neutrophil count <1000; *CBC*, complete blood cell count; *PTLD*, posttransplant lymphoproliferative disease; *RATG*, rabbit antithymocyte globulin; *WBC*, whole blood cell count.

Induction protocols with lympholytic agents OKT3 or antithymocyte globulin are effective in delaying the time until the first allograft rejection episode but do not have a long-term survival benefit.[47] The benefit of induction with IL-2 receptor blockade in preventing early heart allograft rejection is supported by recent studies.[48]

Corticosteroids have been part of standard protocols since the early days of solid organ transplantation. High-dose methylprednisolone (5–10 mg/kg) is administered at the time of aortic cross-clamp removal and continued in tapering doses over the first several days after surgery. Corticosteroids have immunosuppressive properties and benefit the allograft because of membrane-stabilizing and antioxidant effects on the graft.

More controversial is the timing of the introduction of calcineurin inhibitors cyclosporine and tacrolimus. A major complication in the early perioperative course after heart transplantation is renal dysfunction. In the past, calcineurin inhibitors cyclosporine and tacrolimus were major contributors. The APC and lymphocyte

receptor interaction occurs within hours of the transplant; therefore early introduction of calcineurin inhibitors is important. Because bioavailability of these drugs is so variable, early, continuous IV administration of these drugs has been a standard protocol.[49] We continue to experience a group of recipients who develop acute renal failure with IV administration of these drugs and therefore avoid IV use of cyclosporine and tacrolimus. Current protocols are based on oral/nasogastric administration of a standard dose of tacrolimus beginning on the day of transplant. Target levels of this drug are reached 3 to 5 days after transplant if subsequent doses are based on the trough level obtained each morning (see Table 39.1).[50]

The high-risk period for acute cellular rejection (ACR) is the first month after transplantation. ACR is a phenomenon that rarely occurs in the first week after transplant. Hyperacute rejection is uncommon but can occur when a heart transplant recipient has preformed HLA antibody that reacts with a donor who has those specific HLA antigens. A positive crossmatch will be reported, which means the recipient's serum causes lysis of donor T cells obtained from lymph nodes from the donor at the time of organ procurement. Heart transplant recipients at risk for hyperacute rejection are identified by measuring the presence of HLA antibody in their serum. Specificity and quantification of these HLA antibodies can be measured by Luminex beads, which enable a virtual cross-match to be done between potential donors and recipients. Children with palliated congenital heart disease are at particular risk for HLA sensitization because of exposure to blood products at the time of their previous surgical procedures. Rapid institution of plasmapheresis immediately after implantation and continuing through the first several days after the operation is the optimal way to clear the offending antibody causing heart allograft dysfunction.

The diagnosis of ACR is made by endomyocardial biopsy. Histopathology in cardiac tissue obtained by endomyocardial biopsy remains the gold standard for diagnosis of acute cardiac allograft rejection. The numbers of infiltrating lymphocytes and the presence of myocyte injury are used to grade rejection and to guide allograft rejection therapy. Surveillance endomyocardial biopsies are performed within the first 2 weeks after transplant and then at strategic times depending on the size of the child, available access, and technical difficulty of obtaining tissue.

Clinical recognition of acute allograft rejection can be subtle but is obviously important because tissue diagnosis is not always possible, and surveillance techniques using peripheral blood, electrocardiography, and echocardiography have limitations. Acute cellular rejection can be present in the allograft without any symptoms or clinical findings. When ACR has progressed to hemodynamically significant allograft dysfunction, then symptoms of abdominal pain and vomiting are prevalent, and findings of systemic venous congestion, liver enlargement, and low cardiac output dominate. Symptoms of pulmonary venous congestion/pulmonary edema are rare findings. When ACR is suspected, histologic confirmation is always desirable if it can be safely performed. The principles of management are to acutely augment immune suppression with methylprednisolone or a lympholytic agent depending on the histologic and clinical severity of the heart allograft dysfunction. Following acute treatment, increases in maintenance of immune suppression agents are prescribed and follow-up endomyocardial biopsy is scheduled.

Complications of Immune Suppression in Heart Transplant Recipients Occurring in the Pediatric Intensive Care Unit

Infection

Infections are a major cause of mortality and morbidity in the early period after heart transplantation.[51,52] Factors that predispose to infection can be divided into preexisting factors related to the donor and recipient and factors secondary to events in the intraoperative and postoperative periods. For example, the site of the organ transplanted provides a clue to the site of infection. Renal transplant recipients acquire urinary tract infections, whereas heart transplant recipients are exposed to chest cavity infections. The type and severity of the underlying illness leading to organ failure can increase the risk for rejection. Children with cardiomyopathy can be severely malnourished, require prolonged mechanical respiratory or circulatory support, and have chronic indwelling venous catheters, all of which predispose to infection. The presence of a pretransplant pulmonary infarction is associated with lung abscess in the posttransplant recovery period.[53] Neonates may experience severe sepsis from coagulase-positive staphylococci more often than older children.

The herpes virus family plays a significant role in infections occurring after transplantation. The clinical expression of cytomegalovirus and Epstein-Barr virus infection in the young patient is more severe because it is often a primary exposure.[54] Clinical infections related to these viruses rarely present before 1 month following organ transplantation and are most common in the first 6 months after heart transplantation.

Antibiotic management of the heart transplant recipient in the ICU can be focused primarily on clinical suspicion, time of infection after transplant, and predisposing factors. Immune suppression is selective and targets T cells. Neutrophil function is normal except for the effect of high-dose corticosteroids. Neutropenia can occasionally be a problem because of bone marrow suppression caused by antimetabolites and tacrolimus. Prophylactic antibiotics, in the form of third-generation cephalosporins, are used for patients after sternotomy and continued until chest tubes and central lines are removed. The strategy against infection includes initial isolation, routine surveillance cultures, and regular replacement of indwelling catheters. In the early setting after transplantation, temperature elevation should indicate active infection and serious complication. If an infection is suspected, early and aggressive investigation are necessary and broad-spectrum antibiotics/antifungal agents should be initiated until the source of the fever is identified.

Renal Function

Acute renal failure is a major complication following orthotopic heart transplantation. Renal failure is multifactorial in etiology, and the premorbid risk factors of heart transplant recipients cannot necessarily be controlled. We can monitor and control use of calcineurin-inhibitor immune suppression agents. Therapeutic strategies include delayed initiation of cyclosporine and tacrolimus by

using antithymocyte globulin or IL-2 receptor blockade for induction of immune suppression. The other option is to use a modified oral/nasogastric protocol for tacrolimus administration.[55] This protocol targets tacrolimus levels to below 6 ng/mL in the first 3 days after transplantation and then aggressively increases dosing and target level over the next 4 days. It is important to avoid early IV administration of these agents because they invariably lead to renal afferent arteriolar vasoconstriction and oliguria. If renal dysfunction is complicating the posttransplant course, it is still difficult to withdraw calcineurin inhibitors completely, but lowering the target level to less than 6 ng/L and substituting higher doses of mycophenolate mofetil and adding sirolimus are reasonable options.[56] The other means for reversing renal toxicity is to target mechanisms of calcineurin inhibitor toxicity. Renal arteriolar vasoconstriction is an imbalance between vasodilator prostaglandins and vasoconstrictor thromboxane A_2. Thus prostaglandin E1 (PGE1) has been used for promoting renal vasodilatation, with some success. Oral PGE1 analogs have received mixed reviews. Calcium channel antagonists have also been used to prevent renal toxicity. Felodipine has been shown to cause a natriuresis and to prevent the decline in renal hemodynamics produced by angiotensin II. We have not had enough experience with this potentially useful drug in reversing cyclosporine/tacrolimus nephrotoxicity.[57]

Diabetes Mellitus

Hyperglycemia is common after heart transplantation with tacrolimus-based immune suppression. The combination of decreased insulin production from islet cells caused by tacrolimus and decreased peripheral utilization related to high-dose corticosteroids results in nonketotic hyperglycemia. Insulin is initially mandatory in management but often can be discontinued if the tacrolimus dose is reduced and the corticosteroid portion of maintenance immune suppression is discontinued.[58]

Future Management Strategies for Critical Care of Infants and Children With Cardiopulmonary Failure

Heart transplantation in children has gained wide acceptance as an important adjunct to treatment of children with end-stage cardiomyopathic function from cardiomyopathy and palliated congenital heart disease. Successful transplantation has produced longer and better-quality lives for many infants and children. Ten-year survival free of malignancy and coronary vasculopathy is the expected outcome.[59]

The future is moving toward fewer transplant procedures in children. Palliation techniques for complex congenital heart disease (ie, single-ventricle Fontan procedure) are improving, and most of these patients will survive well into adulthood before requiring transplantation. Complications of adolescents with transposition of the great arteries who have undergone a Senning procedure and now present with systemic or right ventricular dysfunction will begin to disappear because of success with the arterial switch.

The natural history of cardiomyopathy is changing because of our understanding

of the cellular mechanisms of myocardial function. New treatment strategies using angiotensin receptor and β-adrenergic blockade therapy are delaying or replacing the need for heart transplantation.

Circulatory support is being miniaturized by the development of the Berlin Heart and the DeBakey centrifugal pump. These devices can cause reversed ventricular modeling, allowing discontinuation of support without heart replacement therapy. The other major benefit of circulatory support is that, if initiated early, it can rehabilitate the child, recover end-organ function, and reduce the risks of heart transplantation surgery.

CHAPTER 40

Acute and Chronic Heart Failure

Meaghan Doherty, Alejandro Lopez-Magallon, Ricardo Munoz

PEARLS

- Admissions for symptoms associated with heart failure in children are common and place a significant burden upon the health care system.
- The etiology for heart failure is diverse, and appropriate therapy is dependent on proper identification of the underlying pathology.
- A solid understanding of cardiac biomechanics and physiology, as well as heart-lung interactions, is vital to proper management of patients in the pediatric critical care setting.
- The value of a comprehensive physical examination in a patient with heart failure is critical, and it should not be underappreciated.
- Echocardiography should be readily available to assess cardiac function, as well as structural or functional abnormalities leading to heart failure.
- When additional diagnostic data are necessary, such as direct measurement of intracardiac hemodynamics, assessment of coronary artery perfusion, or pathologic specimen for histologic diagnosis, cardiac catheterization should not be delayed.
- Targeted therapies may include medical management, catheter-based techniques, or surgical interventions.
- Patients with poor response to conventional medical therapy should be considered candidates for mechanical circulatory support before development of irreversible organ dysfunction.

Heart Failure

There has been increasing awareness regarding the impact of heart failure in pediatric patients and the significant associated morbidity and mortality. Although small in comparison with the numbers found in the adult population, children with heart failure are nowadays overrepresented in hospitals, as they require frequent office visits and unplanned hospital admissions. A recent study from a nationwide

inpatient database estimated 11,000 to 14,000 annual admissions for children with heart failure in the United States.[1] In order to address the clinical needs of these patients, a comprehensive understanding of the underlying pathology and physiology is required, as well as in-depth familiarity with the current treatment options.

Not uncommonly, the patient with heart failure looks relatively well “on the surface” despite significant compromise in ventricular function, and the heart failure cardiologist must observe close vigilance with careful adjustments of anticongestive treatment. When further decompensation occurs, these patients can present a particular challenge to the critical care clinician, who is usually comfortable treating patients with overt hemodynamic compromise with early and invasive interventions. Sometimes delaying highly invasive interventions in order to allow time for improvement or heart transplant under optimal clinical conditions may be indicated, and a careful balance must then be pursued between these two apparently opposing strategies.

Definition

The myocardium functions to pump blood throughout the body in order to deliver oxygen and vital nutrients to the organs, which are necessary to meet systemic demands and maintain homeostasis. Heart failure occurs when the heart can no longer meet the metabolic needs of the body. The underlying pathologies that lead to this clinical syndrome are quite diverse, related to a combination of circulatory, neurohormonal, and molecular abnormalities.[2]

Systolic failure is due to a problem with the heart's ability to generate force during ventricular contraction, whereas diastolic failure is due to inadequate cardiac filling.

The ejection of blood occurs during the contractile phase, or ventricular systole. Problems during this period due to inadequate contractility result in insufficient generation of a pressure differential to drive an adequate blood flow through the body. As there is a deficiency in oxygen delivery and substrate availability, systolic heart failure results.

With diastolic dysfunction, there is impairment in the heart's ability to relax and dilate. A heart with diastolic dysfunction becomes stiff, resulting in elevated filling pressures and therefore a decrease in stroke volume and subsequent decrease in cardiac output. In addition, high atrial pressures develop, leading to pulmonary and systemic venous congestion. In oncology patients, serial echocardiography examinations due to the risk of chemotherapy-induced cardiomyopathy have demonstrated that subtle signs of diastolic dysfunction are often apparent before a decline in systolic dysfunction is evident.[3] Therefore careful assessment of diastolic indices may identify patients who are at increased risk for development of fulminant heart failure.

Although, by convention, the term *heart failure* is most often used to describe conditions in which impaired cardiac output results from derangements in ventricular filling or ejection, conditions of relative cardiac dysfunction may occur when there is increased metabolic demands and the heart is unable to sustain these increased needs.

Causes of Heart Failure

Identification of a primary etiology has important prognostic implications and helps to guide management strategies. Unfortunately, despite a thorough investigation, it is not always possible to determine the exact cause of failure in every patient and broad therapeutic strategies may be employed.

The physiologic circumstances resulting in heart failure are often related to an increased demand on the heart or an abnormality of myocyte structure or cellular regulation. These conditions may be congenital or acquired and may occur in isolation or in combination with other factors. Increased cardiac demands may be categorized as either pressure or volume load.

In children, structural abnormalities related to congenital heart disease are a common feature in patients presenting with heart failure. These abnormalities can result in pressure overload, volume overload, or a combination of both. The variations of lesions that occur are numerous and not discussed at this time. It is important to note that milder lesions may have delayed presentation, and structural heart disease may be found in a previously undiagnosed older child or adult who presents with signs and symptoms of cardiac dysfunction.

Structural abnormalities may be acquired, particularly in the postoperative patient. Septal hypertrophy and ventricular outflow obstruction may occur over time and present in older patients, and valve dysfunction may be a progressive occurrence due to infectious, rheumatologic, toxic, or traumatic insults.

Intrinsic abnormalities of heart muscle structure or metabolism lead to alterations in tissue mechanics or excitation-contraction coupling. These can also occur due to altered physiologic conditions such as electrolyte abnormalities, acidosis, hypoglycemia, or sepsis.

Cardiac arrhythmias can precipitate worsening heart function. This occurs in the presence of atrial or ventricular arrhythmias or complete heart block or may lead to a gradual decline of function due to an initially well-tolerated but incessant rhythm disorder.

High-output cardiac failure results when extra physiologic demands are placed on the myocardium due to an increase in metabolic requirements. This may occur during periods of acute illness or from chronic medical problems such as liver failure. Vascular malformations, such as arteriovenous malformations (AVMs), may also lead to a high-output state.

The myocardium undergoes adaptive mechanisms to accommodate increased workload; however, if these demands persist, the heart may be unable to keep up with the increased demand and dysfunction will result.

Physiologic Consideration in the Patient With Heart Failure

A more extensive discussion on cardiovascular function can be found elsewhere in this book (Chapter 29). Cardiac output is the product of heart rate and stroke volume, which is determined by contractility, preload, and afterload.

Preload

Preload is the amount of blood in the ventricle at the end of diastole. Otto Frank first reported in the late 19th century that stretching the ventricular tissue in frog hearts before contraction increased the strength generated by the myocardium. Later, Earnest Starling and his associates appreciated increased stroke volume in the setting of increasing venous return in dogs. We refer to the Frank-Starling curve as a graphic depiction of the myocardial fibers and ventricular chambers' ability to increase their contractility, and thus stroke volume, in response to changes in preload (Fig. 40.1).

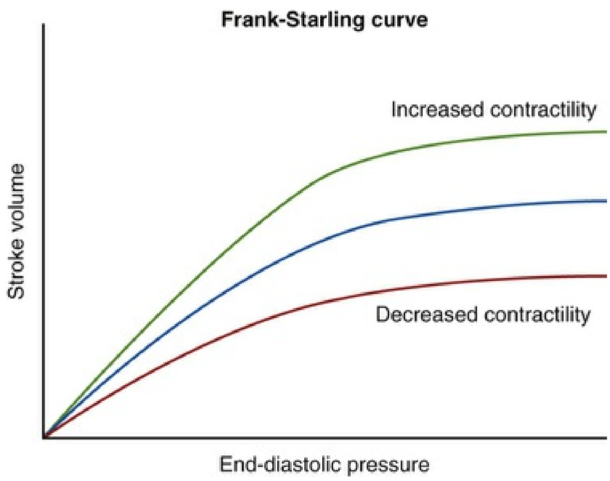

FIG. 40.1 The classic Frank-Starling curve with a graphic depiction of the relationship between preload and stroke volume under different inotropic conditions. For any given increase in preload (end-diastolic pressure), there will be a corresponding increase in stroke volume until a point of overstretching, beyond where there is a change in the slope with decreasing changes in stroke volume for any given increase in preload.

This concept holds true until a certain point at which the myocardial fibers become overstretched and the length-tension relationship is no longer optimal for maximum contraction. At this point there is a change in slope of the curve to reflect a decrease in pressure generation at higher volumes. Clinically this represents the point where administration of additional fluid results in worsening symptoms of congestion. Another limitation of this graph is that it does not demonstrate the changes that occur in end-systolic volume with altered venous return. When afterload and contractility are kept stable, a pressure-volume loop can be used to demonstrate how changes in intraventricular volume affect pressure in the ventricle throughout the cardiac cycle (Fig. 40.2).[4]

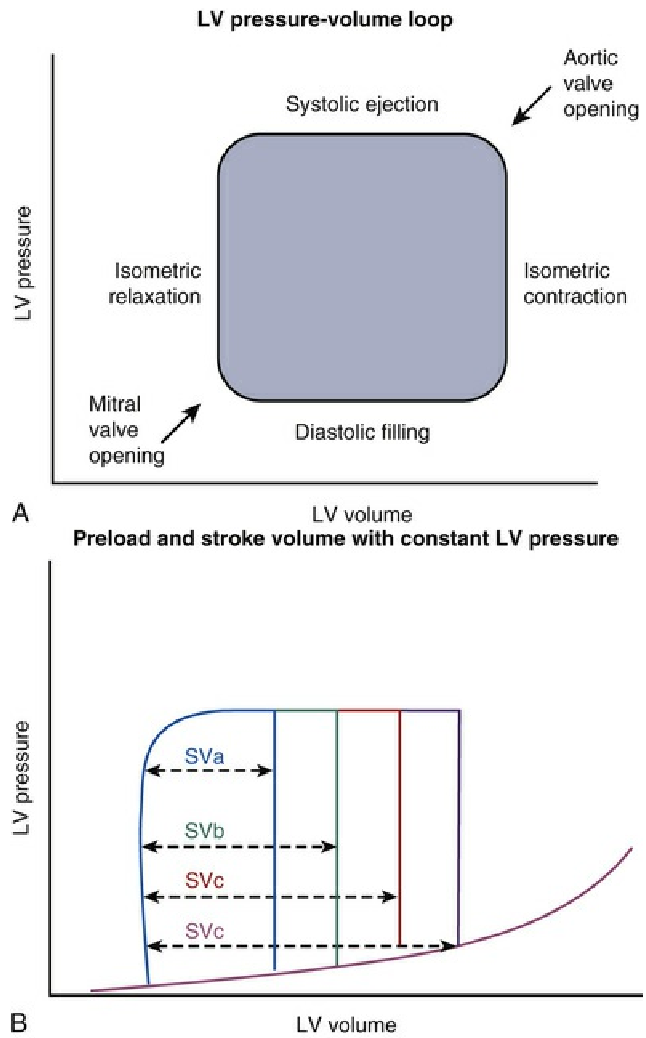

FIG. 40.2 Preload and stroke volume at constant left ventricular (LV) systolic pressure. (A) LV pressure-volume loop. Left ventricular pressure is plotted multiple times against chamber volume during the cardiac cycle. (B) Hemodynamic parameters like stroke volume, cardiac output, ejection fraction, and myocardial contractility can be determined from loop analysis.

If left ventricular pressure continues to rise at end diastole, several undesired effects occur. First, pulmonary congestion will develop with associated symptoms of cough, shortness of breath, and tachypnea. Worsening pulmonary edema may lead to poor gas exchange and decreased oxygenation. In addition, as stroke volume increases, so does wall tension and afterload. As the coronary arteries fill during diastole, coronary perfusion may become impaired by the increasing afterload and, combined with the increased oxygen consumption by the myocardium under these circumstances, may lead to tissue ischemia.

Afterload

Afterload can be thought of as the pressure or resistance against which the heart must pump in order to eject blood during systole. In the absence of left ventricular or aortic stenosis, the major determinant of the amount of force needed is the systolic blood pressure. Although systolic blood pressure plays a major role in cardiac

afterload, it is not the only variable at play. Afterload is better defined by the concept of wall stress, also called systolic wall tension (SWT), which accounts for intraventricular pressure, as well as both ventricular radius and ventricular wall thickness. As the ventricle dilates and its radius increases, there is an increase in wall stress. Conversely, when there is an increase in wall thickness, wall stress is reduced. This relationship is defined by the Law of LaPlace:

$$SWT = \frac{(transmural\ pressure \times ventricular\ radius)}{(wall\ thickness \times 2)}$$

Contractility

Contractility is the intrinsic ability of the heart muscle to generate force, and it occurs at the level of the sarcomere, where cross-bridge connections between actin and myosin filaments are formed. In the resting state, calcium is stored in the sarcoplasmic reticulum and the adenosine triphosphate (ATP) binding sites of the myofilaments are covered. When calcium is released into the cytosol in response to cell membrane depolarization, it triggers a conformational change that results in exposure of ATP binding sites and allows binding between the thick and thin filaments.

Cardiac contractility is dependent on many factors including the structural integrity of myocardial fibers, proper electrolyte balance, adequate energy sources, and preload, as previously discussed. Alterations in cellular metabolism include a transition from fatty acid utilization to glucose metabolism. Mitochondrial dysfunction and free radical formation have a deleterious effect on excitation-contraction coupling and heart muscle mechanics.[5]

Oxygen Delivery

Oxygen delivery is the amount of oxygen delivered to the tissues each minute and is calculated by cardiac output multiplied by arterial oxygen content. The oxygen content of blood is determined by the hemoglobin concentration, hemoglobin saturation, and the amount of oxygen dissolved in the blood. This is another important concept to consider when managing a patient with poor cardiac output, as avoidance of anemia is a key treatment strategy.

Assessment of the Patient With Heart Failure

The development of low cardiac output syndrome (LCOS) can be assessed by both invasive and noninvasive means. Historic data including events preceding patient presentation and important features such as decreased urine output should be discussed. The clinical presentation will vary considerably with age, and these differences should be appreciated. Whereas infants may present with irritability or poor feeding, older children often complain of abdominal pain or discomfort.

Physical Examination in Patients With Heart Failure

A thorough physical examination is an essential part of the assessment of children with heart failure, perhaps more so than the typical patient in the critical care environment. The reliance on invasive monitoring alone may be insufficient to a complete understanding of a patient's status.

The physical examination begins with visual inspection of the patient and assessment of vital signs. Changes in heart rate or respiratory rate may be the earliest signs of a struggling myocardium; an altered heart rate may suggest underlying dysrhythmia. Changes in blood pressure may occur as a late manifestation of heart failure but are an important indicator of cardiac output. Respirophasic variation in pulse pressure should be noted, as this may suggest problems such as cardiac tamponade, and a wide pulse pressure may reflect a worsening aortic valve insufficiency. Oxygen saturation should be followed closely, as poor oxygenation may indicate worsening cardiac output or lung disease. In fact, this tool is often used to screen neonates for the presence of congenital heart disease. A pulse oximetry reading of less than 95% requires additional investigation.[6] In patients with mixed circulations, it is useful to estimate the amount of pulmonary blood flow.

During inspection, a patient's color, presence of dysmorphic features, level of alertness, and any visual signs of distress, such as increased work of breathing, should be noted. Patients in severe heart failure may have a pale or ashen discoloration. Overt cyanosis or digital clubbing will arise suspicion of preexistent cyanotic heart disease or pulmonary hypertension with right-to-left shunting. Assessment of peripheral perfusion including pulses, temperature, and capillary refill is critical. Cool extremities with a warm core may be found in patients who are volume depleted or have a low cardiac output. Jugular venous distension may be difficult to identify in younger patients but is best assessed with the head of the bed at a 30-degree angle.

A careful respiratory examination is indicated in all patients. Changes in voice, cry, or audible stridor may suggest vocal cord dysfunction, whereas asymmetric chest movement is indicative of diaphragm paresis. Percussion and asymmetric breath sounds may help identify the presence of a pleural effusion. Rales during auscultation are suggestive of pulmonary edema, whereas wheezes or rhonchi suggest coexisting lung disease. Alternatively, wheezing can be appreciated in patients with airway compression due to vascular malformations or left atrial enlargement.

A focused cardiac examination begins with observation of the chest. Surgical scars offer a clue to preexisting pathology. Abnormal pulsations and displaced point of maximum impulse (PMI) should also be noted. The presence of a hyperdynamic precordium suggests a volume-overloaded heart, which can occur in the setting of increased intracardiac shunting or regurgitant valve function. A thrill may be appreciated due to high-velocity blood flow through a stenotic valve, vessel, or restrictive shunt. Pulses should be assessed in all extremities. Decreased pulsation in one extremity may suggest peripheral arterial thrombosis or may be due to a prior surgery such as a classic Blalock-Taussig shunt or subclavian flap repair of coarctation. Simultaneous palpation of upper and lower extremity pulses should be performed to assess for femoral delay secondary to a coarctation.

Auscultation of the heart should first focus on the rate and regularity of the heartbeat. The second heart sound should have variable splitting with respiration, although this may not be noted in the first day or two of life due to elevated

pulmonary vascular resistance. A single heart sound is otherwise abnormal and may be due to valve atresia, pulmonary hypertension, or transposition of the great vessels. A second heart sound that is widely split is due to changes that delay closure of the pulmonary valve, such as right-sided volume overload or a right bundle branch block, whereas a narrow split S2 is found in conditions that result in early closure of the pulmonary valve or delayed closure of the aortic valve. Paradoxic splitting can occur with severe aortic stenosis.

Extra heart sounds can be either benign or pathologic. Although a third heart sound may be a normal finding in older children, a gallop rhythm with a third or fourth heart sound may reflect a stiff or volume overloaded ventricle, especially if accompanied with other signs and symptoms of heart failure. A fourth heart sound may be noted in late diastole and is nearly always abnormal, usually due to filling of a poorly compliant ventricle. Early systolic clicks suggest stenosis of a semilunar valve and are more easily appreciated when a patient leans forward. A midsystolic click suggests mitral valve prolapse, although this finding is uncommon in children. A pericardial friction rub is more easily appreciated over the apex and is common in the early postoperative period, although in the setting of recent-onset heart failure it may be due to acute myocarditis. A rub may not be appreciated in the presence of a large effusion.

Finally, careful assessment of organomegaly is required for a complete evaluation. Liver congestion and engorgement occurs due to high systemic filling pressures, and liver distension can be monitored over time to assess the patient response to anticongestive treatment. Care must be taken to distinguish true hepatomegaly from a downward displaced liver in the setting of pulmonary hyperinflation. This can often be distinguished by use of percussion.[7]

Diagnostic Studies in Patients With Heart Failure

A 12- or 15-lead electrocardiogram should be performed promptly in addition to continuous telemetry monitoring to assess for conduction abnormalities or other derangements in rhythm that can lead to rapid decompensation.

Biomarkers

Cardiac biomarkers are frequently used in the identification and surveillance of children with heart failure. The expanding field of metabolomics looks to identify metabolic differences in patients with early versus overt heart failure. The most commonly recognized and frequently utilized biomarkers are the natriuretic peptides (NPs), which are released from cardiac tissue in response to increased stress related to elevated pressure and/or volume load. Four NPs have been identified: A, B, C, and D. In clinical practice, brain natriuretic peptide (BNP), which is primarily secreted from the ventricle, is the most commonly measured peptide. NT-proBNP is a bioproduct of the BNP prohormone and can also be measured. These peptides function to decrease afterload by blocking endothelin release and promote diuresis and natriuresis by inhibiting the renin-angiotensin-aldosterone system. BNP has been found to have vasodilatory effects in the systemic, pulmonary, and renal blood

vessels.[8]

In addition to being useful in the initial diagnosis of heart failure, these levels can be trended over time to monitor a patient's clinical status and response to therapy. Elevated BNP was found to be a risk factor for both readmission and death in a study of children with decompensated heart failure.[9]

The normal BNP level is appreciably elevated in the first few days of life, and normal values fall throughout the neonatal and childhood periods. These values also vary with patient size and gender and may be elevated in the setting of decreased clearance related to renal disease. It is important to remember that these levels may also be elevated in the setting of other diseases that cause increased demands on the heart, such as persistent pulmonary hypertension of the newborn or diaphragmatic hernia.

A study by Cheng et al.[5] evaluated plasma metabolite profiles using mass spectroscopy in control patients versus those with heart failure and those considered to be in recovery. A number of the metabolites investigated, particularly histidine, phenylalanine, spermidine, and phosphatidylcholine, were found to have independent prognostic significance similar to BNP, and analysis of these and other metabolites in combination was found to have improved prognostic value compared with BNP alone.

Echocardiography

Echocardiography is a vital tool in the evaluation of patients with cardiac dysfunction, offering a quick and comprehensive anatomic assessment, as well as determination of myocardial performance. Quick access to echocardiography is key to the assessment of a patient with changing hemodynamic circumstances, and identification of underlying etiology allows for timely initiation of targeted therapy. Measures of cardiac function include assessment of contractility, ejection fraction, and shortening fraction. Diastolic function can be investigated by tissue Doppler indices, and valve dysfunction can be demonstrated by color Doppler interrogation.

We focus specifically on measurements of global cardiac function. It is important to acknowledge that there are limitations to these tools, which do not assess for regional wall motion abnormalities or dyskinesis, which are particularly important when there is local injury suggestive of a coronary perfusion defect. In addition, these localized areas of dysfunction may not be properly accounted for in the calculations of global function and often add imprecision to the measurements. This is why a simple number is not sufficient to adequately describe overall cardiac performance, and these indices should be used together for an improved clinical picture.

Flow across the aortic valve can be quantified and used to estimate cardiac output. This is performed by obtaining a pulsed Doppler envelope at the level of the valve annulus in order to determine the velocity-time integral (VTI). This value is a correction for the change in velocity that occurs during the ejection time and is calculated by the computer. The VTI can then be multiplied by the cross-sectional area at the valve annulus to give an estimate of the stroke volume.[10] Once stroke volume is determined, it is multiplied by the patient's heart rate to determine cardiac output.

Determination of ejection fraction is based on the differences of ventricular

chamber volume in diastole and systole, so errors associated with these volume measurements affect the estimated ejection fraction. The volume measurements are dependent on assumption of a normal ventricular shape, which is not necessarily true in hearts with significant dilation or hypertrophy. In addition, accurate measurement requires distinction between the cardiac wall and chamber interface, which is open to observer error, as well as issues related to image quality. Similar errors in these measurements are more dramatic in smaller patients. Left ventricle (LV) volume is calculated by 5/6 × LV length × cross-sectional area. LV ejection fraction is the percent change in ventricular volume between end diastole and end systole. The measurements are performed in the apical window using either the two- or four-chamber view. Normal estimated ejection fraction is between 54% and 75%.[10]

Right ventricle (RV) measurements are even more challenging due to its complicated geometry and the difficulty with two-dimensional (2D) imaging of this complex structure. Magnetic resonance imaging (MRI) is frequently used for more definitive analysis of RV size and function. Fractional area change (RV FAC) is a frequently used echocardiographic measurement to assess RV systolic function. It is measured as RVEDA-RVESA/RVEDA, where RVESA is RV end-systolic area and RVEDA is RV end-diastolic area. One important limitation to this calculation is that it does not account for the outflow portion of the RV, which is not visualized in the apical four-chamber view, where this measurement is performed. The use of three-dimensional echocardiography has been found to be more accurate compared with 2D echocardiography when compared with MRI measurements of RV size and function.[10] As the orientation of the muscle fibers in the RV is aligned to contract in a more longitudinal plane, the degree of tricuspid valve systolic excursion during RV systole, known as TAPSE, correlates well with other measures of RV function. This is performed by obtaining an M-mode tracing through the lateral aspect of the tricuspid valve annulus in the apical view. Values can be interpreted as z scores on the basis of patient age and size.[11]

Shortening fraction (SF) is the percent change in the LV dimension from end diastole to end systole: LVEDD-LVESD/LVEDD × 100, where LVEDD is LV end-diastolic dimension and LVESD is LV end-systolic dimension. The normal value for LVSF is 28% to 38% and is highly dependent on ventricular loading conditions.[10]

Valve function should first be evaluated using 2D imaging. Valve size, leaflet excursion, and presence of infravalvar or supravalvar narrowing or dilation should be appreciated. Once the anatomy of the apparatus is established, color Doppler may be placed along the trajectory at an appropriate Nyquist limit, and turbulence of flow by color aliasing or presence of valvar insufficiency should be noted. Next spectral Doppler using both pulsed and continuous wave Doppler should be performed with the angle of interrogation parallel to the direction of blood flow. A pulsed Doppler signal will assess velocity at the specific level along the plane of interrogation, whereas a continuous wave Doppler will assess the velocities along the entire plane of interrogation. Thus it may be difficult to identify the precise level of obstruction using only continuous wave; however, the highest velocity along the trajectory will be determined. The velocities measured using spectral Doppler can be converted to pressure gradients using the Bernouli equation. Interpretation of these values must give consideration to the patient's hemodynamic state, as decreased contractility will result in lower valve velocities and potential underappreciation of valve stenosis, whereas hyperdynamic states may overestimate these gradients.

Additional Noninvasive Imaging Modalities

Although echocardiography is relatively quick, available, and inexpensive, there are many times when all of the desired information cannot be obtained from this modality alone and additional diagnostic tools should be considered. Other imaging modalities, such as MRI or CT scans, are frequently used to clarify a patient's anatomy when it is not clearly demonstrated by echocardiogram. This is the case when suboptimal images are obtained due to poor acoustics or when a question remains regarding coronary artery anatomy or anomalous venous drainage. Cardiac MRI is also useful for volume quantification and assessment of RV function,[12] which can be particularly challenging to assess by echocardiography. A myocardial perfusion scan to assess for delayed enhancement should be obtained when there is concern for regional ischemia related to impaired coronary blood flow.[13]

Cardiac Catheterization

Ready access to a cardiac catheterization laboratory with a skilled interventional cardiologist is necessary when direct measurement of intracardiac pressures is indicated, such as when a patient's course is not progressing as expected. Calculations of cardiac output, pulmonary vascular resistance, and Qp : Qs can be performed using data acquired in the cardiac catheterization laboratory to give a precise assessment of cardiac hemodynamics.

Cardiac catheterization is considered the gold standard for assessment of coronary perfusion and is also useful for assessing pulmonary venous desaturation secondary to pulmonary AVMs. Catheterization is also preferred over noninvasive studies when there is an indication for intervention, such as balloon atrial septostomy, angioplasty or valvotomy, or if a myocardial biopsy is required. Some patients may require emergent intervention, as may occur in a baby with transposition of the great arteries and acidosis secondary to a restrictive atrial septum. A more detailed analysis of catheter-based hemodynamic assessment and interventions is given in Chapter 32.

Management of Low Cardiac Output Syndrome

Medical management is used in acute heart failure to improve oxygen delivery capabilities to increase perfusion to vital organs.

Preload Management

Volume should not be withheld with the intention of preventing of edema in the setting of multiorgan dysfunction. Correction of the metabolic imbalances is of primary importance. Diuretics are indicated to limit the resulting pulmonary edema and require close monitoring of electrolyte imbalances and renal function. Acute kidney injury is a common and dose-related adverse effect from overaggressive diuresis. Most cases of acute kidney injury are reversible; however, particularly in patients with poor cardiac output and renal perfusion, irreversible renal damage may occur. Acute kidney injury is associated with increased risk of dialysis, prolonged intubation, infection, and prolonged ICU length of stay.[14]

Methods to Reduce Afterload

Systemic vascular resistance can be decreased by the use of vasodilators, as discussed in more detail later, thus decreasing ventricular workload. The use of mechanical ventilation is a powerful tool to reduce transmural pressure and therefore systolic wall tension and afterload in patients with decompensated heart failure (Fig. 40.3).

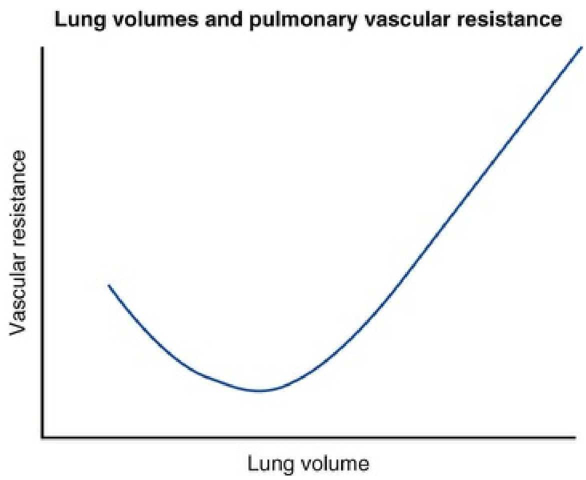

FIG. 40.3 Lung volumes and pulmonary vascular resistance. At constant transmural pressure of the capillary bed, there is high resistance at low lung volumes due to stretching of extra-alveolar space. As lung volumes increase, the capillaries increase in diameter. Further increase in lung volumes will stretch the capillaries, resulting in narrowed vessel caliber.

Methods of Optimizing Contractility

Inotropic agents are frequently used to enhance myocardial contractility. Factors to consider when choosing an inotrope include the resultant increase in myocardial oxygen consumption, its impact on the conduction tissue and propensity for arrhythmias, the effect on both systemic and pulmonary vascular resistance, and the specific type of heart disease being treated.

Oxygen Consumption

Oxygen consumption is the amount of oxygen consumed by the body. Because this value is equal to the amount of oxygen exchanged at the lungs, oxygen consumption can be measured via indirect calorimetry. In practice, the Fick principle is more commonly used to estimate oxygen consumption as the product of cardiac output and the difference in oxygen content between the arterial and venous systems. As increased cardiac output is necessary to compensate for relative anemia, maintenance of adequate hemoglobin is critically important in managing patients with heart failure.

Pharmacology of Heart Failure

Diuretics are used to manage systemic and pulmonary congestion. Although diuretics can provide marked symptomatic improvement, they do not affect contractility or afterload and are often used in conjunction with other agents. Loop diuretics are the most potent and rapid-acting diuretics and are therefore the drugs of choice in the ICU setting. See Table 40.1 for dosing guidelines.[15] They act by inhibiting the sodium-potassium-chloride cotransporter in the ascending limb of the Loop of Henle, resulting in decreased sodium and chloride resorption. Other classes of diuretics such as thiazide and aldosterone antagonists may be used as adjunctive therapy to augment diuresis.

TABLE 40.1

Inotropic Drugs

Drug	Dose	Site of Action/Receptor	Effect
Calcium chloride	Bolus: 5-10 µg/kg Infusion: 10 mg/kg/hr	Cardiac myofilaments	↑ Contractility & SVR May ↑ PVR, ↓ HR
Epinephrine	0.01-0.05 µg/kg/min	β > α	↑ HR & contractility ↓ $_{renal}$VR, may ↓ PVR & SVR
	>0.05 µg/kg/min[a]	α1 > β	↑ SVR
Norepinephrine	0.01-0.3 µg/kg/min[a]	α1 > β	↑ HR, contractility, SVR & PVR, ↓ $_{renal}$VR
Dobutamine	2-10 µg/kg/min	β1 > β2, α1	↓ HR, contractility ↓ SVR & PVR
	10-20 µg/kg/min		
Dopamine	2-5 µg/kg/min	DA1, DA2	↓ $_{renal}$VR
	5-10 µg/kg/min	β > α1	↑ HR, contractility, $_{renal}$VR
	10-20 µg/kg/min[a]	α1 > β	↑ HR, contractility, SVR, PVR, $_{renal}$VR
Isoproterenol	0.01-0.2 µg/kg/min	β1, β2	↑ HR, contractility ↓ SVR, PVR, $_{renal}$VR
Milrinone	0.25-1 µg/kg/min Optional loading dose: 75-100 µg/kg	Phosphodiesterase III inhibitor	↑ HR, contractility ↓ SVR, PVR, $_{renal}$VR
Levosimendan	Bolus: 6-12 µg/kg Infusion: 0.05-0.1 µg/kg/min	Troponin C, ATP-sensitive K+ channels	↑ contractility ↓ SVR, PVR, $_{renal}$VR No effect on HR

[a]Higher doses may be used, but increase in cardiac afterload may be detrimental to myocardial performance.

HR, heart rate; SVR, systemic vascular resistance; PVR, pulmonary vascular resistance.

From Jones M, Klugman D, Fitzgerald R, et al. Pediatric Cardiac Intensive Care Handbook, Diuretics. Washington, DC: Pediatric Intensive Books, LCC; 2015 and Biaggioni I, Robertson D. Adrenoreceptor agonists and sympathomimetic drugs. In: Katzung BG, Masters SB, Trevor AJ, eds. Basic and Clinical Pharmacology. 11th ed. Stamford, CT: McGraw-Hill; 2009:127-148.

Acute kidney injury is a serious and unfortunately common complication of diuretic use. Additional side effects of diuretics include electrolyte and acid-base imbalances. Hypokalemia, hypocalcemia, hypomagnesemia, and hypochloremic alkalosis may occur in a dose-dependent fashion. Hence close monitoring of renal function and electrolytes is indicated with use of these medications, with electrolyte repletion as indicated.

Vasoactives

Adequate calcium balance is necessary for proper cardiac muscle performance due to its role in excitation-contraction coupling. Avoidance of hypocalcemia,

particularly in neonates who have a poorly developed sarcoplasmic reticulum, is crucial to optimize cardiac function and maintain proper vascular smooth muscle tone. Patients who have undergone cardiac bypass or have received large volumes of blood products are at particular risk for hypocalcemia. Monitoring ionized calcium levels is necessary to determine the need for supplemental calcium administration, as elevated intracellular calcium levels have been associated with increased cell injury and death during ischemia and reperfusion. Calcium infusion may lead to bradycardia, particularly if done rapidly. Calcium administration is not recommended in patients with preexisting bradycardia or asystole unless there is established hypocalcemia or hyperkalemia. In addition, caution must be used in patients on digoxin as calcium may enhance digitalis toxicity. See Table 40.2 for dosing guidelines and effects of the most commonly used vasoactive medications.[16,17]

TABLE 40.2
Diuretics

Drug	Dosing	Oral		IV/IM	
Furosemide	Neonates & preterm	1-4 mg/kg/dose	Every 12-24 hours	1-2 mg/kg/dose	Every 12-24 hours
	Infants & children	0.5-6 mg/kg/day	Divided q 6-12 hours	0.5-4 mg/kg/day	Divided q 6-12 hours
	Adults	20-80 mg per dose	Every 6-8 hour	20-40 mg/dose; may increase by 20 mg	May repeat as needed
Bumetanide	Neonates	0.01-0.05 mg/kg/dose	Every 24-48 hours	0.01-0.05 mg/kg/dose	Every 24-48 hours
	Infants & children	0.015-0.1 mg/kg/dose	Every 6-24 hours; max: 10 mg/day	0.015-0.1 mg/kg/dose	Every 6-24 hours; max: 10 mg/day
	Adults	0.5-2 mg/dose	Every 12-24 hours; max: 10 mg/day	0.5-1 mg/dose	Every 6-24 hours; max: 10 mg/day

IM, intramuscular; IV, intravenous.

Dopamine has a dose-dependent response on various tissues within the body. At low doses the dopaminergic-1 receptors are activated within the renal, mesenteric, and coronary vasculature. This so-called “renal dosing” of dopamine increases renal blood flow and glomerular filtration rate but is a controversial concept not universally accepted. At moderate doses there is activation of the B1 receptors in the heart, which has both inotropic and chronotropic effects. This results in increased cardiac output but minimal increase in blood pressure due to the peripheral vasodilatory effects of the dopaminergic receptors. As the medication is titrated to higher doses, there is activation of peripheral $\alpha 1$ receptors, as well as stimulation of endogenous norepinephrine release from nerve endings, both of which result in increased peripheral systemic vascular resistance (SVR) and cardiac afterload.[16] One concern with use of dopamine in infants is the potential pituitary gland suppression and alteration of thyroid function.[16,18]

Dobutamine acts primarily on $\beta 1$ adrenergic receptors with less effect on $\alpha 1$ and $\beta 2$ receptors. Therefore cardiac output is augmented by increased heart rate and contractility, with little to no increase in SVR, making this medication more appropriate for use in cases of cardiac dysfunction. However, increase in myocardial oxygen consumption may aggravate diastolic dysfunction in some patients.

Milrinone is a phosphodiesterase III inhibitor, which increases cAMP and results

in increased calcium within the cardiac myocytes, improving both systolic and diastolic cardiac function. In addition to increased contractility, milrinone results in peripheral vasodilation by relaxing vascular smooth muscle cells. Therefore cardiac output and oxygen delivery are augmented without an increase in myocardial oxygen demand. Prophylactic milrinone therapy has been found to reduce the incidence of postoperative LCOS by up to 55% in neonates undergoing congenital heart surgery.[19] Milrinone may result in hypotension and reflex tachycardia. Slow-dose titration may be preferable to use of a loading dose to avoid an acute drop in blood pressure. Milrinone has a relatively long half-life, particularly in patients with renal dysfunction, and its effect persists for hours after its discontinuation.

Epinephrine has strong α and β effects, and its effect on different tissues within the body is also dose dependent. Low-dose epinephrine increases blood pressure primarily by increasing cardiac contractility by activation of the β1 receptor. There is also an effect on β2 receptors in skeletal muscle tissue that decreases vascular resistance and reduces cardiac afterload. As epinephrine dosing is titrated upwards, there is a greater effect on peripheral α receptors, resulting in increased blood pressure and cardiac afterload. There is an increase in renal vascular resistance at all doses, leading to risk of renal insufficiency due to diminished renal blood flow. Like most vasoactive medications, epinephrine can be proarrhythmic and continuous telemetry monitoring during infusion is required. The patient is at risk for both atrial and ventricular ectopy and reentrant tachycardias due to increased automaticity, as well as decrease in atrioventricular (AV) nodal refractory time. In addition, high-dose infusions of epinephrine can cause cardiac tissue necrosis in young infants and alternative methods of support should be considered should high doses be required.

Norepinephrine acts similarly to epinephrine; however, it is a more potent vasoconstrictor. There is little effect on peripheral β2 receptors, and therefore small doses of norepinephrine result in increased SVR and blood pressure, as opposed to low-dose epinephrine, which can decrease SVR. Norepinephrine also has a strong effect on β1 receptors within the heart to increase contractility, similarly to epinephrine. Norepinephrine is best indicated in cases of circulatory collapse and hypotension not responsive to other pressors. However, it is less commonly used in young children with cardiac dysfunction due to the significant increase in afterload.

Levosimendan works by altering the protein structure of troponin C and making it more sensitive to intracellular calcium, leading to increased inotropy without associated increase in myocardial oxygen consumption. It also results in vasodilation by increasing the activity of potassium-ATPase of the sarcolemma of smooth muscle tissue and provides a cardioprotective effect by acting on the same channel in the cardiac myocyte mitochondria. Its primary indication is in the treatment of acute-onset heart failure. Several ongoing prospective trials are looking at use of levosimendan in the immediate postoperative period with some encouraging results, and an experimental animal model comparing levosimendan with milrinone found similar and even advantageous effects of levosimendan in systemic and pulmonary vasodilation, as well as myocardial oxygen consumption profile.[20] The most common adverse effects include hypotension, tachycardia, atrial fibrillation, hypokalemia, and headache.

Isoproterenol is a nonselective β agonist with minimal α activity. Its physiologic effect is increased heart rate and contractility with decreased SVR. There is a greater chronotropic than inotropic effect, and isoproterenol is useful in patients with

symptomatic bradycardia or heart block. Isoproterenol should be avoided in patients with ventricular outflow tract obstruction due to decreased preload. Significantly increased myocardial oxygen consumption may lead to demand ischemia, and high doses are associated with ventricular arrhythmias.

Mechanical Circulatory Support

Greater detail on the application, physiology, and technical issues of the various circulatory support devices are given elsewhere (Chapter 30). Unfortunately there are currently no established guidelines on the use of various methods of mechanical circulatory support in children and, therefore, the indications for and use of these devices vary widely across institutions. Overall, there seems to be a trend toward increased reliance on these devices as technology, surgical technique, and clinical outcomes have improved.[21]

The typical indication for mechanical circulatory support is when continued clinical decompensation is present despite highly aggressive medical management. Signs and symptoms that may be present under these circumstances include increased work of breathing, poor perfusion or other signs of LCOS, such as decreased mixed venous oxygenation, a rising base deficit or lactate levels, acidosis, and signs of multiorgan dysfunction such as decreased urine output or a change in neurologic status. When less invasive therapies are unable to correct these abnormalities, discussions regarding escalation of care among the multidisciplinary care teams should occur under semielective conditions and before further clinical deterioration that will lead to circulatory collapse and cardiac arrest.

The risk undertaken when deploying these devices can be substantial and must not be underappreciated. Infection is an obvious risk, and maintaining a low index of suspicion for sepsis with frequent surveillance cultures and judicial use of broad spectrum antibiotics is vital. Thrombosis is a common complication, and a strict anticoagulation protocol with full heparinization should be followed, unless medically contraindicated, in addition to close inspection of the visible portions of the circuit for thrombus formation or stranding.[22]

The successful management of a patient on mechanical circulatory support is best accomplished through the collaboration of a highly skilled interdisciplinary care team. Diligent bedside nursing combined with knowledgeable perfusionists, technically skilled surgeons, and an attentive intensive care team is necessary to provide the highest level of care to these most critically ill patients.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) requires surgically placed inflow and outflow cannulas in the major blood vessels or within the cardiac chambers. This can be done either centrally via a median sternotomy or by a vascular cutdown approach. Echocardiography is often used as an adjunct to confirm adequate cardiac decompression and cannulae position.

As many ECMO candidates may have congenital vascular anomalies or a history of previous vessel instrumentation in the cardiac catheterization laboratory or with central vascular access devices, knowledge of the anatomy, patency, and continuity of the vessels that may be chosen for ECMO cannulation is imperative before the

procedure itself so as to avoid futile attempts and delays. ECMO can be rapidly instituted in patients with worsening cardiac dysfunction as a bridge to longer-term mechanical support using a ventricular assist device (VAD) or as a bridge to transplantation.

The use of VA ECMO has seen a dramatic increase. Once thought to be a last-effort salvage therapy for dying patients, ECMO is now used more routinely, particularly in larger centers. Because a patient's prognosis following ECMO is highly dependent on the patient's status before initiation of bypass, including organ dysfunction, residual cardiac lesions, or shunts and underlying disease pathology, it may be advantageous to consider initiation of ECMO sooner when the medical status of a patient is deteriorating, before development of multiorgan dysfunction, as these patients may have improved outcome following recovery of myocardial function or easier transition to longer-term therapies.[23]

ECMO allows time for ventricular recovery by decompressing the heart and lowering wall stress, improving coronary perfusion and supporting the circulation with adequate oxygenation. Of course, if the heart is not participating in cardiac output whatsoever, over time the heart muscle will atrophy, making the ability to wean from ECMO less likely. Just as early initiation and utilization of ECMO are key to prognosis, so too is an early exit strategy for weaning and ultimate decannulation in patients with recovery potential.

Managing Patients on ECMO

Immediately following successful cannulation and initiation of ECMO, systemic perfusion should be assessed and cannulae position should be confirmed. Mixed venous oxygenation, lactate levels, central venous pressure, blood pressure, and urine output are all critical components of an ongoing assessment and should be closely monitored with optimization of circuit flow rates and cardiac output, as indicated.

The patient should be monitored for signs of left atrial hypertension due to inadequate decompression as this may require placement of a left atrial vent to reduce wall stress and facilitate myocardial recovery. This can be evaluated on chest radiograph, echocardiogram, and by clinical examination findings suggestive of pulmonary edema.

As previously discussed, avoidance of anemia is necessary to optimize oxygen content and delivery. A higher flow rate needed to compensate for the presence of anemia leads to increased cell damage and hemolysis within the circuit. Hemoglobin of 14 to 15 gm/dL is considered optimal. A platelet count of at least 75,000 to 100,000 is considered adequate to minimize risk of bleeding.[24] As discussed earlier, a strict adherence to anticoagulation protocol to maintain optimal heparinization and minimize risk of thrombosis is critical.

Causes of decreased venous drainage may be related to hypovolemia in the setting of bleeding or fluid shifts, but sudden changes may signal compromised flow through the venous catheter, development of pericardial tamponade, or pneumothorax and mandate rapid investigation.

Echocardiography can be used to assess for cardiac distention and wall motion during attempts at weaning of ECMO flows and in observation of cardiac function during transient interruption of ECMO flows (clamping and bridging). Once

underlying disease processes have been addressed and the patient is able to successfully wean flows and tolerate clamping, decannulation from ECMO should not be delayed.

Ventricular Assist Devices

VADs can be categorized as either continuous or pulsatile. Continuous flow ventricular assistance is provided by various types of centrifugal devices that are operated by a rotating magnet that drives a continuous roller pump. Cannulation for a centrifugal pump device is akin to that used for ECMO and can be used in most sizes of patients, including infants. The long-term risks of a centrifugal VAD are the same as a patient cannulated onto ECMO, and they are best used for short-term management as a bridge to recovery. However, due to the lack of an oxygenator and generally shorter tubing length, these devices have lower thrombotic risk compared with an ECMO circuit. Therefore the anticoagulation goals for a patient on a centrifugal pump can be less aggressive, which in turn may reduce the risk of bleeding. Patients are unable to ambulate with these devices, and like all mechanical support devices, shorter duration of support is associated with improved outcomes.[21]

Pulsatile VADs can be used for longer duration and are indicated in patients with persistent symptoms of low cardiac output or end-organ dysfunction on maximal support, often as a bridge to transplantation. This may include patients unable to wean from ECMO. Placement of a pulsatile device requires central cannulation through a midline sternotomy incision. Improved cardiac output and oxygen delivery result in improved end-organ perfusion. In addition, patients are able to ambulate and participate in higher levels of physical rehabilitation, which can improve pretransplant status. Unloading the heart with this type of device may allow for improved myocardial recovery. These devices are not currently approved as destination therapy in children, although they have been used for this indication in adults.

The external pulsatile VAD should be physically examined multiple times each day. The inlet and outlet valves of the bladder are a common location for thrombin stranding and clot formation, so careful inspection is critical. The membrane should be inspected for persistent wrinkling, which generally indicates inadequate bladder filling or ejection. Insufficient filling may reflect poor intravascular volume status, inadequate negative diastolic pressure, or development of cardiac tamponade. Inadequate bladder ejection suggests increased afterload, which may be related to clot formation, cannulae placement, patient agitation, or infection. Use of vasodilators or inotropic agents may be necessary to augment cardiac output under these circumstances.[21]

Heart Transplantation

Heart transplantation is the preferred treatment option in patients with advanced heart failure and inability to wean from higher levels of support, including continuous intravenous infusions or mechanical circulatory support.[25] Heart transplantation is best performed in a high-volume center with a dedicated multidisciplinary care team consisting of heart failure and transplant cardiologists,

transplant nurse coordinators, social workers, pharmacists, nutritionists, and psychologists specially trained in the unique issues relative to this patient population.

The evaluation process for a potential transplant candidate is extensive and involves assessment of comorbid medical problems, infectious issues, alloimmunization status, as well as social and psychologic concerns. Any potential contraindications to transplantation must be explored carefully. Patient nutrition, rehabilitation status, and vaccinations should be optimized before transplantation, although live vaccines should be avoided due to immunosuppression at the time of transplantation.

When an organ becomes available, critical assessment of donor suitability is conducted, including cause of death, structure, function, rhythm abnormalities, and size of the donor relative to the recipient, as well as direct inspection of the organ at the time of procurement. An actual or virtual crossmatch for compatibility between the donor and recipient is also performed. Hyperacute rejection, which is due to preformed antibodies, is a rare but devastating complication. Acute humoral rejection often occurs days to weeks following transplantation but is much less common than acute cellular rejection. The most common cause of death in the early postoperative period is primary graft failure, which can be detected by lymphocyte infiltration on endomyocardial biopsy. Ischemia times of greater than 3 hours are associated with a higher risk of primary graft failure.[26]

Two techniques are commonly used for surgical anastomosis of the transplanted heart. The original technique used by Lower and Shumway involves anastomosis of the recipient atria with that of the donated heart. An alternative method involves venous anastomosis of the superior vena cava, inferior vena cava, and the right and left pulmonary veins. This approach may be better in patients who have undergone surgical palliation for congenital heart disease and results in less AV valve regurgitation and atrial arrhythmias; however, the procedure is more time consuming and has the added risk of acquired venous obstruction. A hybrid approach in which the left atrium is anastomosed as in the biatrial technique, together with complete resection of the recipient's right atrium and bicaval anastomosis as in the “total transplantation technique,” has also been performed.[25] It is important to know which approach is used so that potential postoperative complications can be anticipated.

Intraoperative transesophageal echocardiogram is used to monitor cardiac function and potential complications, particularly right heart function and narrowing at the anastomosis sites. Poor cardiac function or rhythm abnormalities may require ECMO cannulation in some patients.

Postoperative management involves close attention to rhythm issues, fluid status, postoperative bleeding, and markers of hemodynamics including central venous pressures, mixed venous oxygen saturation, serum lactate, and urine output. Hypotension is common and may be due to LCOS or from systemic inflammatory process. Causes of LCOS include hypovolemia, cardiac tamponade, and poor ventricular function, as well as rhythm issues including bradycardia and atrial tachycardia. Temporary epicardial pacing or antiarrhythmics may be indicated. Echocardiography can also be useful in identifying primary cardiac causes. If corrective measures are not taken in a timely manner, secondary organ dysfunction will result. Care to avoid fluid overload in the early postoperative period is

necessary to avoid exacerbation of right ventricular failure. Surgical reexploration or mechanical support may be indicated in some cases.

Immunotherapy

Use of induction of immunosuppression, which drastically reduces the likelihood of rejection in the early postoperative period, varies across different centers in terms of the patient selection and therapies used. Some centers use induction therapy on all patients, while others reserve this for those considered at higher risk of rejection. Use of induction allows delayed initiation of oral immunosuppression agents until renal and GI function have improved, yet it has been found to be associated with increased risk of later rejection.[26]

When used, induction should ideally begin within the first 12 hours, after postoperative bleeding is controlled. Steroid therapy is generally given in the operating room and continued throughout the postoperative period. Two commonly used induction agents are monomurab-CD3 (OKT3), which is a mouse monoclonal antibody, and antithymocyte globulin (RATG), which is a polyclonal rabbit antibody. Efficacy is similar between the two agents with different risk profiles. Risks include bacterial and viral infection and posttransplant lymphoproliferative disorder (PTLD).[25] Interleukin-2 receptor antibodies basiliximab and daclizumab, initially used in renal transplant patients, have also been employed after cardiac transplantation and seem to have a decreased risk of infection compared with older agents.[26] Maintenance immunosuppression with oral medications can be started following induction in so-called “sequential therapy.” Some centers prefer to start these agents sooner, either in place of or at the time of induction therapy. Maintenance therapy generally consists of a calcineurin inhibitor, either cyclosporine or tacrolimus, which inhibits T-cell activation. Tacrolimus may be superior at preventing acute graft rejection when used in combination therapy. Calcineurin inhibitors are typically used in conjunction with an antiproliferative agent such as mycophenolate or azathioprine, which both interfere with purine synthesis. Mycophenolate has been associated with decreased mortality at 1 and 3 years relative to azathioprine.[25]

Conclusion

Management of patients with heart failure requires persistent ongoing assessment, with analysis of hemodynamic data and other contributing factors or underlying disorders. When a patient's clinical course is not as anticipated, rapid and sometimes highly invasive means are indicated to obtain additional diagnostic information to allow for specific targeted therapy. Maintenance of adequate cardiac output with avoidance of acidosis and multisystem organ dysfunction is the primary objective, and when this cannot be achieved with medical management alone, additional measures including use of mechanical circulatory support should be pursued. Although heart transplantation is a last-resort therapy, patients who require high levels of support without reasonable potential for recovery should be considered early, before development of irreversible organ damage or other risk factors that would worsen overall prognosis or deem them ineligible for organ listing.

CHAPTER 41

Physiologic Foundations of Cardiopulmonary Resuscitation

Adnan M. Bakar, Kenneth E. Remy, Charles L. Schleien

PEARLS

- Both the cardiac and thoracic pump mechanisms play a role in infants and children during cardiopulmonary resuscitation, so attention to excellent chest compression technique with an emphasis on "push hard, push fast" is critical to attaining sufficient cardiac output to maintain coronary and cerebral blood flow.
- Use of any vasoconstrictor (including vasopressin) should be sufficient to raise aortic diastolic pressure during cardiopulmonary resuscitation above the critical level for resuscitation success (>15–20 mm Hg).
- Amiodarone or lidocaine may be the most effective pharmacologic treatment for shock-resistant ventricular tachycardia or fibrillation.
- Use of the biphasic defibrillator is an important advance in the treatment of tachyarrhythmias and has advantages in its safety profile compared with monophasic defibrillators.
- Post–cardiac arrest resuscitative care is critical to survival and includes appropriate uses of inodilators and neuroprotective strategies, including avoidance of hyperthermia.

With the development of basic cardiopulmonary resuscitation (CPR) in the early 1960s, skilled resuscitation teams both in and out of the hospital were formed. The development of CPR saved lives; previously, every victim of cardiac arrest had died. Soon thereafter, successful resuscitation of patients by basic life support measures, defibrillation, and medications became common, even as long as 5 hours after commencement of CPR. Over the past decade, both survival and neurologic outcomes after in-hospital cardiac arrest have improved in adults and children.[1-3] Data show that the success of CPR depends on many factors. Rapid institution of basic life support measures (ie, bystander CPR for sudden out-of-hospital cardiac

arrest and immediate electrical countershock for ventricular fibrillation [VF]) improve the chances of survival for patients experiencing sudden out-of-hospital cardiac arrest.[4] These measures led to the growing deployment of automatic external defibrillators (AEDs) in public places. Immediate defibrillation is currently the standard of care in witnessed VF arrests. However, evidence indicates that basic life support and other measures directed at restoring energy substrates to the myocardium before countershock in patients with unwitnessed, out-of-hospital arrest may further improve outcome.[5-8]

Other preexisting factors that play a role in successful resuscitation include the patient's age, prior medical condition, presenting cardiac rhythm, and etiology of cardiac arrest. In 2008, a multi-institutional prospective study was published that examined these preexisting factors and further described in two additional studies the clinical characteristics, hospital course, and outcomes of a cohort of children after in-hospital or out-of-hospital arrest. Besides demonstrating differences in clinical characteristics, these studies offered future considerations for the care of children who had experienced cardiac arrest and post resuscitative care, including hypothermia.[9-11] The low resuscitation rate in children, even when the patient does not have preexisting disease, probably results from the high incidence of asystole as the presenting rhythm. Asystole is the most common presenting rhythm in both in-hospital and out-of-hospital arrests and is noted in 25% to 70% of victims.[12-16] Bradycardia and pulseless electrical activity (PEA) are other common rhythms. The high incidence of asystole in children who experience cardiac arrest can be explained by systemic disturbances such as hypoxia, acidosis, sepsis, and hypovolemia that commonly precede the arrest. Although ventricular arrhythmias are usually reported to be infrequent (range, 1.3%–3.8%), out-of-hospital series report VF in 10% to 19% of victims younger than 20 years.[17,18] These series, along with the observation that the frequency of witnessed arrest is much lower than in adults, suggests that ventricular rhythms may be more common than usually estimated and that delay in resuscitation results in progression of nonperfusing rhythms to asystole. Increasing availability of AEDs may be contributing to the increased recognition of ventricular arrhythmias in out-of-hospital pediatric cardiac arrest.[19] In specialized cardiac ICUs, ventricular arrhythmias account for as many as 30% of the arrests.[3,20,21]

In their original work on CPR, Kouwenhoven et al.[22] proposed that blood flow during closed-chest compressions resulted from squeezing of the heart between the sternum and vertebral column, now termed the *cardiac blood flow mechanism.* In fact, the precise mechanism by which forward circulatory flow is generated during closed-chest cardiac massage has major implications for current approaches to CPR. Other methods, such as vest CPR, simultaneous compression ventilation CPR (SCV-CPR), active compression-decompression CPR (ACD-CPR) both without and with an impedance threshold valve (ITV), and interposed abdominal compressions with CPR (IAC-CPR), take into account advances in our understanding of the mechanism of blood flow during resuscitation.

The pharmacology of resuscitation remains controversial, and these controversies have led to major changes in the guidelines for CPR. Use of sodium bicarbonate, calcium chloride, and glucose remains unresolved at this time. The role of high-dose epinephrine has been minimized because of concerns over postresuscitation deleterious effects on myocardial performance and poor outcomes. Evidence favoring a role for vasopressin, with a relatively pure vasoconstrictor effect, is

accumulating. The role of lidocaine as the antiarrhythmic of choice for ventricular ectopy has been questioned as new data on the efficacy of amiodarone in persons in cardiac arrest have been generated.[3] Research is ongoing into alternative vasoconstrictors and the use of "pharmacologic cocktails" that may include β-blockers, antiarrhythmic agents, antioxidants, nitroglycerin, and a vasoconstrictor in attempts to improve the resuscitation outcome and postresuscitation cardiac function.[23-25]

Developments in the use of direct current countershock have occurred. Biphasic defibrillators are now widely in use and appear to improve the success of defibrillation at lower delivered energies and, it is hoped, decrease myocardial injury. As noted, the role of "shock first" is being reassessed because the success of electrical countershock in restoring spontaneous circulation declines rapidly after 3 to 4 minutes have elapsed.

Although postresuscitation cerebral preservation has become an important area of focus, therapeutic hypothermia has not been found to improve neurologic outcome after pediatric cardiac arrest.[11]

This chapter discusses the physiologic foundations of CPR. In the first section, the possible mechanisms of blood flow by the thoracic and cardiac pump mechanisms are discussed, including how the specific chest geometry of children and infants helps decide which of these mechanisms applies. Then newer CPR techniques, which take into account the physiologic mechanisms discussed in the first section, are discussed. Controversies and advances in pharmacologic management during CPR and current guidelines for use of drugs for resuscitation are addressed. New developments in the use of countershock, including the timing of shocks, the energy used, and the type of current delivery system used (biphasic or monophasic), are discussed. Finally, the role of therapeutic hypothermia is reviewed.

Mechanisms of Blood Flow

Cardiac Versus Thoracic Pump Mechanism

The cardiac pump hypothesis holds that blood flow is generated during closed-chest compressions when the heart is squeezed between the sternum and vertebral column. This mechanism of flow implies that ventricular compression causes closure of the atrioventricular valves and that ejection of blood reduces ventricular volume. During chest relaxation, ventricular pressure falls below atrial pressure, allowing the atrioventricular valves to open and the ventricles to fill. This sequence of events resembles the normal cardiac cycle and occurs during cardiac compression when open-chest CPR is used.

Numerous clinical observations have conflicted with the cardiac pump hypothesis of blood flow. In 1964, Mackenzie et al.[26] found that closed-chest CPR produced similar elevations in arterial and venous intravascular pressures, the result of a generalized increase in intrathoracic pressure.[26] In 1976, Criley et al.[27] made the dramatic observation that several patients in whom VF developed during cardiac catheterization produced enough blood flow to maintain consciousness by repetitive coughing (Fig. 41.1). The production of blood flow by increasing thoracic pressure without direct cardiac compression describes the thoracic pump mechanism of blood flow during CPR.

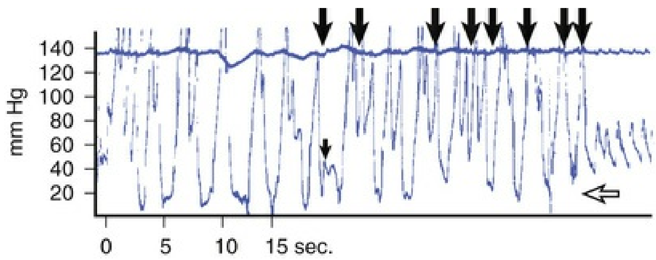

FIG. 41.1 Cough-cardiopulmonary resuscitation during prolonged ventricular asystole after coronary arteriographic injection. An 18-second period of asystole after right coronary arteriographic injection is depicted. During this period, the patient coughed every 2 seconds, generating peak aortic pressures greater than 140 mm Hg. *Large arrows* mark the intrinsic QRS complexes after the 18-second period of asystole. The *Small arrow* marks the resultant aortic pressure from the first intrinsic beat. The patient continued to cough until the cardiac rhythm stabilized 40 seconds later. (From Criley JM, Blaufuss AH, Kissel GL. Cough-induced cardiac compression. Self-administered form of cardiopulmonary resuscitation. JAMA. 1976;263:1246.)

During normal cardiac function, the lowest pressure in the vascular circuit occurs on the atrial side of the atrioventricular valves. This low pressure compartment is the downstream pressure for the systemic circulation, which allows venous return to the heart. Angiographic studies show that blood passes from the vena cava through the right heart into the pulmonary artery and from the pulmonary veins through the left heart into the aorta during a single chest compression.

Echocardiographic studies show that, unlike normal cardiac activity or during open-chest CPR, during closed-chest CPR in both dogs and humans, the atrioventricular valves are open during blood ejection and aortic diameter decreases rather than increases during blood ejection.[28,29] These findings during closed-chest CPR support the thoracic pump theory and argue that the heart is a passive conduit for blood flow (Fig. 41.2).[30]

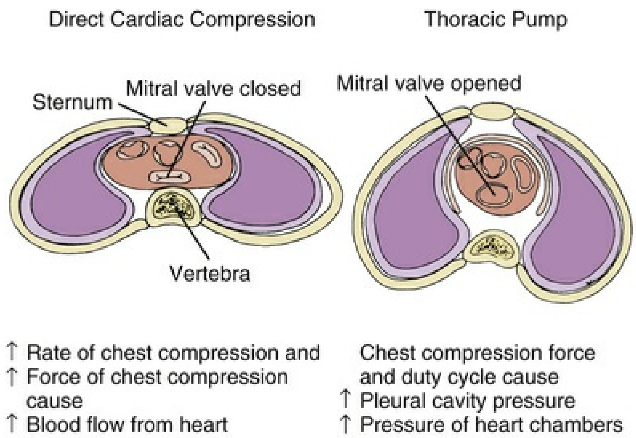

FIG. 41.2 Possible mechanisms for blood flow during cardiopulmonary resuscitation include direct cardiac compression *(left)* and the thoracic pump *(right)*. With direct cardiac compression, an increase in chest compression rate causes an increase in blood flow by squeezing the heart between the vertebral column and sternum. With the thoracic pump mechanism, factors that increase pleural pressure cause an increase in pressure within the heart chambers and ultimately an increase in blood

flow. (From Schleien CL, et al. Controversial issues in cardiopulmonary resuscitation. Anesthesiology. 1989;71:135.)

Initial measurements of hemodynamic data during chest compression for CPR found the generation of almost equal pressures in the left ventricle, aorta, right atrium, pulmonary artery, and esophagus (Fig. 41.3).[31] The finding that all intrathoracic vascular pressures are equal implies that suprathoracic arterial pressures must be higher than suprathoracic venous pressures. The unequal transmission of intrathoracic pressure to the suprathoracic vasculature establishes the gradient necessary for blood flow. The transmission of intrathoracic pressure to the suprathoracic veins may be modulated by venous valves. The presence of these jugular venous valves has been demonstrated in animals and humans undergoing CPR.[32-34] An ultrasonography study of healthy children confirmed the presence of these valves in 84% of 239 jugular veins studied. The valves were bilateral in 74% of children.[35] Transmission of intrathoracic pressure to the intracranial vault during CPR indicates that any such valve function is partial. Pathologic studies have also identified valves in the subclavian vein in the large majority of cadavers studied (87%). The absence of these valves in some patients is postulated to lead to failure of closed-chest CPR.[36]

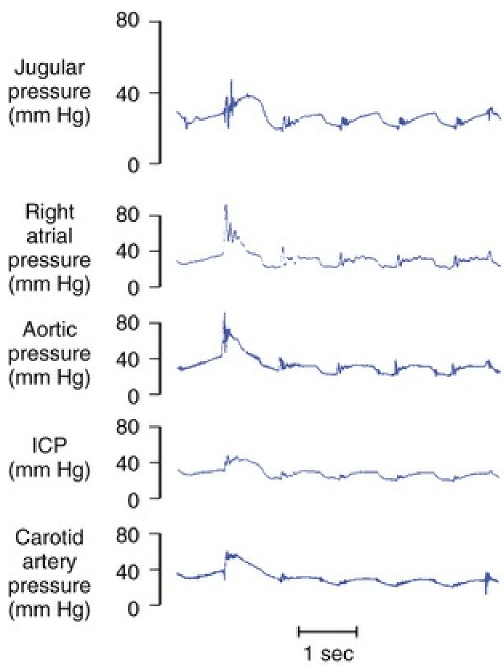

FIG. 41.3 Original record during conventional cardiopulmonary resuscitation. The first compression for conventional cardiopulmonary resuscitation follows the lung inflation that occurred during the previous release phase. Note increase in pressure on this compression. *ICP*, intracranial pressure. (From Koehler RC, Chandra N, Guerci AD, et al. Augmentation of cerebral perfusion by simultaneous chest compression and lung inflation with abdominal binding after cardiac arrest in dogs. Circulation. 1983;67:266.)

Subsequent hemodynamic and echocardiographic studies found different results. Deshmukh et al. demonstrated in a porcine model that mitral valve function persisted throughout resuscitation in 17 of 22 animals and that in successfully

resuscitated animals, maximal aortic pressure exceeded that in the right atrium throughout the resuscitation.[32] In another porcine model of resuscitation, Hackl et al. manipulated the compressive force and depth of resuscitation by using a mechanical resuscitator.[37] The frequency of mitral valve closure during compressive systole was directly proportional to the force and depth of chest compression. When the depth of compression reached 25% of the anteroposterior diameter, valve closure occurred in 95% of cycles. They concluded that the mechanism of blood flow was dependent on the force and depth of compression. In a study of CPR using transesophageal Doppler echocardiography in adults, Porter et al. demonstrated mitral valve closure in compressive systole in the majority of patients (12 of 17) but not all patients.[38] Peak mitral flow occurred in diastole and was significantly higher in the group with mitral valve closure. Peak mitral flow occurred during compressive systole in those without valve closure. Left ventricular fractional shortening correlated with change in anteroposterior chest wall diameter and not mitral valve flow. These authors concluded that nonuniform increased intrathoracic pressure plays a role in determining whether valve closure occurs during chest compressions. As noted, a decrease in aortic dimension during CPR has been demonstrated by echocardiography and taken as evidence for the thoracic pump mechanism of blood flow. Hwang et al. readdressed this issue using transesophageal echocardiography.[39] They studied the aortic dimension of the proximal and distal thoracic aorta and noted a decrease in the aortic dimension in the distal aorta directly inferior to the zone of direct compression and an increase in the dimension of the proximal aorta. They also noted mitral valve closure in all subjects and a decrease in left ventricular (LV) volume of almost 50% at end compression. These findings were believed to be most consistent with the cardiac pump mechanism of blood flow.[40] Kim et al. also used transesophageal echocardiography to explore the role of the LV during nontraumatic arrests.[41] They noted that during the compression phase of CPR, there was anterograde flow from the ventricle to the aorta, as well as retrograde flow toward the mitral valve. The mitral valve remained closed during compression and opens during relaxation, while the aortic valve remained open during compression and closed during relaxation, which they concluded to be consistent with the cardiac pump mechanism.

The cardiac pump mechanism appears to predominate during closed-chest CPR in specific clinical situations. As noted, increasing the applied force during chest compressions increases the likelihood of direct cardiac compression. A smaller chest size may allow for more direct cardiac compression.[37,41] Adult dogs with small chests have better hemodynamics during closed-chest CPR than do dogs with large chests. Because the infant chest is smaller and more compliant than the adult chest, direct compression of the heart during CPR is more likely to occur. Blood flow during closed-chest CPR in a piglet model of cardiac arrest is higher than that achieved in adult models.[42] In contrast to adult animals, increasing intrathoracic pressure by SCV-CPR does not augment vascular pressure or regional organ blood flow during CPR in piglets.[43] The failure of SCV-CPR to increase blood flow in the infant implies that direct compression occurs with conventional CPR and that additional intrathoracic pressure is of no benefit. In a more recent study of 20 randomized swine to either a patient-centric blood pressure targeted approach with titration of compression depth to a systolic blood pressure of 100 mm Hg and vasopressors to a coronary perfusion pressure greater than 20 mm Hg or current usual practice, the

blood pressure targeted group demonstrated improved 24-hour survival (8/10 vs. 0/10 survival, $p = 0.001$).[44] This study suggests that physiologic targets rather than absolute depths by age may in fact confer better outcomes.

Rate and Duty Cycle

In 2015 the American Heart Association (AHA) recommended a rate of chest compressions of at least 100 per minute.[45-49] At faster rates, blood flow is enhanced whether the thoracic pump mechanism or the cardiac pump mechanism is invoked. Duty cycle is defined as the ratio of the duration of the compression phase to the entire compression-relaxation cycle expressed as a percent. For example, at a rate of 30 compressions/min, a 1.2-second compression time produces a 60% duty cycle. If blood flow is generated by direct cardiac compression, then the stroke volume is determined primarily by the force of compression. Prolonging the compression (increasing the duty cycle) beyond the time necessary for full ventricular ejection should have no additional effect on stroke volume. Increasing the rate of compressions should increase cardiac output because a fixed, relatively small volume of blood is ejected with each cardiac compression. In contrast, if blood flow is produced by the thoracic pump mechanism, the volume of blood to be ejected comes from a large reservoir of blood contained within the capacitance vessels in the chest. With the thoracic pump mechanism, flow is enhanced by increasing either the force of compression or the duty cycle but is not affected by changes in compression rate over a wide range of rates.[33] Additionally, the "push hard, push fast" recommendation is based on the maintenance of a higher compression rate with a higher force of compression. Allowing total recoil of the chest allows for full blood return during the relaxation phase of the cycle.[50]

Mathematic models of the cardiovascular system confirm that blood flow is determined by both the applied force and the compression duration with the thoracic pump mechanism.[51] A mathematic model equating CPR to a circuit, constructed by Babbs, determined that while hemodynamics did not vary with compression rate, total flow and coronary flow were greatest when compression time equaled 30% of cycle time.[52]

It appears from experimental animal data that both the thoracic pump and cardiac pump mechanisms can effectively generate blood flow during closed-chest CPR. Differences between various studies may be attributed to differences in animal models or compression techniques. Important differences in animal models include chest wall geometry, compliance and elastic recoil, compliance of the diaphragm, and intraabdominal pressure. Differences in technique include the magnitude of sternal displacement, compression force, and momentum of chest compression, compression rate, and duty cycle. Experimental and clinical data support both mechanisms of blood flow during CPR in human infants.

Results of several studies in dogs demonstrated a benefit of a compression rate of 120 per minute compared with slower rates during conventional CPR.[53-54] In studies of piglets, puppies, and humans, no differences were found comparing different rates of compression during conventional CPR.[34,55-57] In a study of piglet CPR, duty cycle was the major determinant of cerebral perfusion pressure. The duty cycle at which venous return became limited varied with age. A longer duty cycle was more effective in younger piglets.[57] In a more recent study of 22 pigs randomized to either

head-up tilt versus supine CPR using an automated CPR device plus an impedance threshold device after VF arrest, cerebral perfusion pressure and intracranial pressure improved substantially with head-up tilt position.[58] This suggests that gravity has an effect on the venous circulation with high quality CPR and head tilted up positioning on cerebral perfusion. The discrepant importance of rate and duty cycle in various models (by different investigators) is confusing. However, increasing the rate of compressions during conventional CPR to 100 per minute satisfies both those who prefer the faster rates and those who support a longer duty cycle. This is true clinically because producing a longer duty cycle is easier when compressions are administered at a faster rate.

Chest Geometry

Chest geometry plays an important role in the ability of extrathoracic compressions to generate intrathoracic pressure. Shape, compliance, and deformability, which change greatly with age, are the chest characteristics that have the greatest impact during CPR.

The change in cross-sectional area of the chest during anterior to posterior delivered compressions is related to its shape (Fig. 41.4).[59] The ratio of the chest anteroposterior diameter to the lateral diameter is referred to as the *thoracic index.* A keel-shaped chest, as seen in an adult dog, has a greater anteroposterior diameter and thus a thoracic index greater than 1. A flat chest, as in a thin human, has a greater lateral diameter and thus a thoracic index less than 1. A circular chest has a thoracic index equal to 1. A circle has a larger cross-sectional area than either of these elliptical chests. As an anteroposterior compression flattens a circle, the cross-sectional area decreases and compresses its contents. In contrast, as an anteroposterior compression is applied to the keel-shaped chest, the cross-sectional area increases as a circular shape is approached. The cross-sectional area of the keel-shaped chest does not decrease until the chest compression continues past the circular shape to flatten the chest. This implies a threshold past which the compression must proceed before intrathoracic contents are decreased and squeezed.[59] Thus the rounder, flatter chests of small dogs and pigs may require less chest displacement than the keel-shaped chests of adult dogs to generate thoracic ejection of blood. This dynamic has been demonstrated in small dogs having round chests compared with adult dogs having keel-shaped chests.[60]

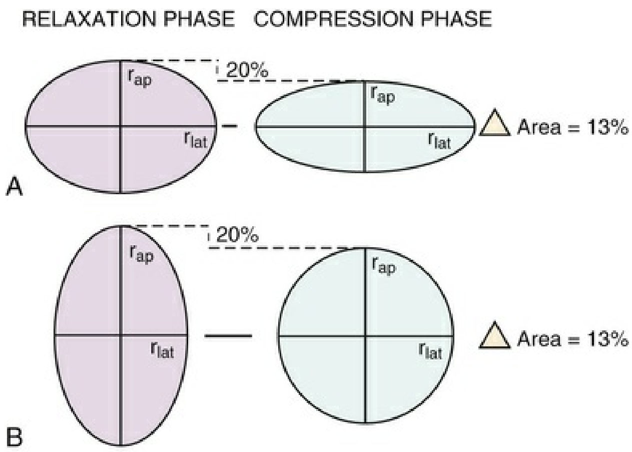

FIG. 41.4 Changes in area of ellipses with constant circumference. Each ellipse is labeled with the anteroposterior *(ap)* and lateral *(lat)* radii, and a 20% anteroposterior compression is applied. Indicated change in area equals relaxed area–compressed area. (A) Initial anteroposterior/lateral ratio = 0.7, and compression leads to positive ejection because relaxed area–compressed area is negative. (B) Initial anteroposterior/lateral ratio = 1.4, and compression toward a circular shape results in an increase in area. (From Dean JM, Koehler RC, Schleien CL, et al. Age-related changes in chest geometry during cardiopulmonary resuscitation. J Appl Physiol. 1987;62:2212.)

As humans age, the cartilage of the rib cage calcifies and chest wall compliance decreases. Older patients may require greater compression force to generate the same sternal displacement. A 3-month-old piglet requires a much greater compression force for anteroposterior displacement than its 1-month-old counterpart.[59] Direct cardiac compression is more likely to occur in the more compliant chest of younger animals. Cerebral and myocardial blood flow during closed-chest CPR were much higher in infant piglets than in adults (Figs. 41.5 and 41.6).[61] This finding supports the cardiac pump mechanism of blood flow in infants because the level of organ blood flow achieved during closed-chest CPR in piglets approaches the level achieved during open-chest cardiac massage in adults.

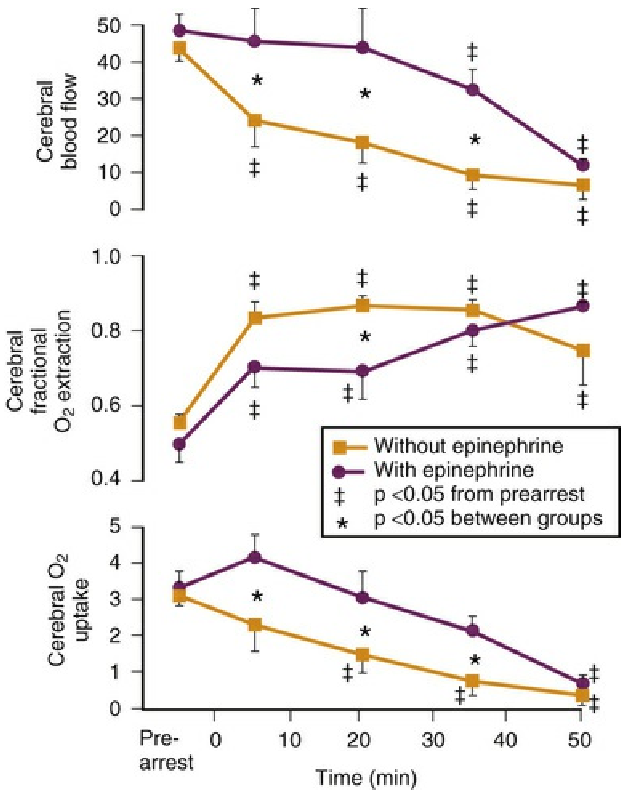

FIG. 41.5 Total cerebral blood flow, cerebral fractional O_2 extraction, and cerebral O_2 uptake before cardiac arrest and during 50 minutes of cardiopulmonary resuscitation in the groups with and without epinephrine.

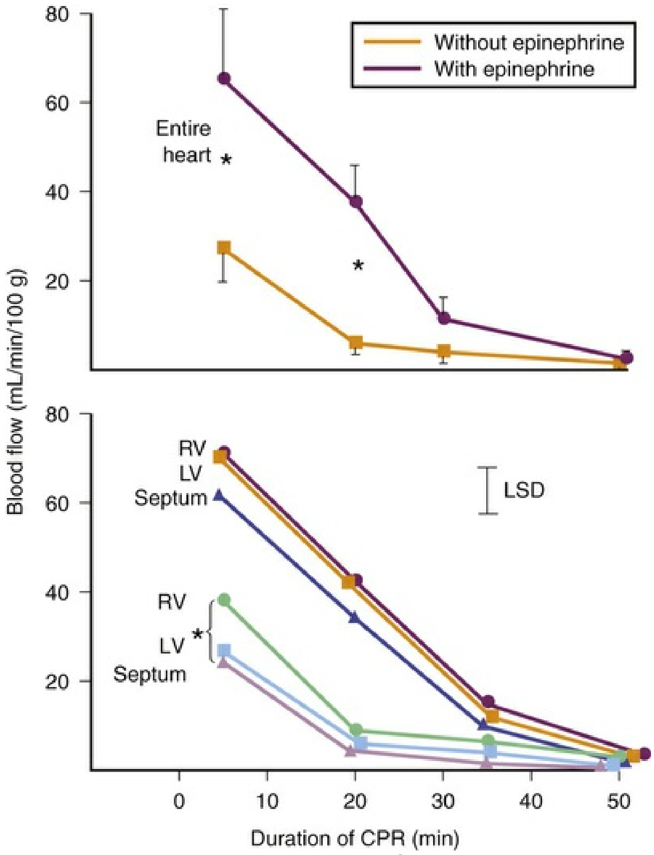

FIG. 41.6 *Top,* Total myocardial blood flow during cardiopulmonary resuscitation (CPR) in piglets with and without epinephrine. *Asterisk* indicates significant difference between groups at 5 and 20 minutes. *Bottom,* Blood flow to right ventricular free wall *(RV, circle),* left ventricular free wall *(LV, squares),* and interventricular septum *(triangles)* in the groups with and without epinephrine. Standard error bars are omitted for clarity, but the least significant difference bar (*LSD,* derived from Duncan multiple-range test) is shown for comparisons among heart regions within an animal group. (Means must differ by height of bar for $p < .05$.) LSD for comparing means between groups is twice that shown for within-group LSD. *Asterisk* indicates that RV blood flow was greater than LV and septal blood flows at 5 minutes in the group without epinephrine. Flows in all three regions in the group with epinephrine were greater than those in the respective regions in the group without epinephrine at 5 and 20 minutes. (From Schleien CL, Dean MJ, Koehler RC, et al. Effect of epinephrine on cerebral and myocardial perfusion in an infant animal preparation of cardiopulmonary resuscitation. Circulation. 1986;73:809.)

Marked deformation of the chest can occur during prolonged CPR and may alter the effectiveness of CPR (Fig. 41.7).[61] Over time, the chest assumes a flatter shape, producing a larger percent decrease in cross-sectional area at the same absolute chest displacement. Progressive deformation may be beneficial if it leads to more direct cardiac compression. Unfortunately, too much deformation may decrease the recoil of the chest wall during the relaxation phase, leading to decreased cardiac filling. A progressive decrease in the effectiveness of chest compressions to produce blood flow is seen in piglets receiving conventional CPR.[61] Permanent deformation of the chest in this model approaches 30% of the original anteroposterior diameter. Attempting to limit deformation by increasing intrathoracic pressure from within

during CPR with SCV-CPR was ineffective.[61] Using a thoracic vest to limit deformation when performing CPR greatly decreased the permanent chest deformation (3% vs. 30%) but did not attenuate the deterioration of vital organ blood flow with time.[63]

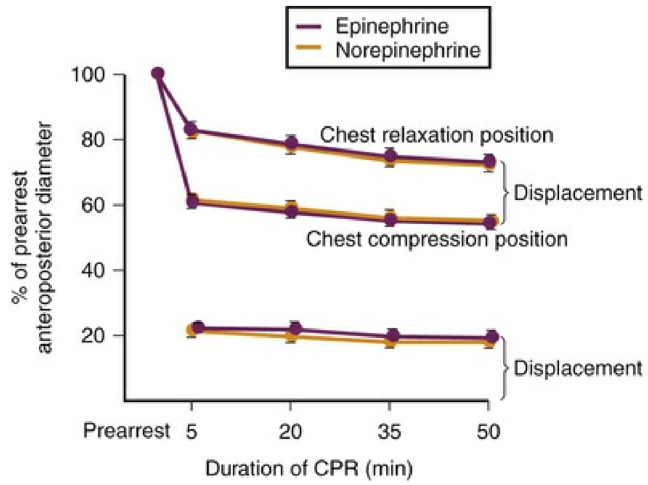

FIG. 41.7 Piston position during chest compression and relaxation phases of the cycle and net piston displacement expressed as a percent of prearrest anteroposterior chest diameter (12.0 ± 0.3 cm) in piglets. Note that displacement was essentially unchanged over the 50-minute duration, but marked deformation occurred during the relaxation phase by 5 minutes and continued to further deform over the 50-minute period in the groups with or without epinephrine. *CPR*, cardiopulmonary resuscitation. (From Schleien CL, Dean MJ, Koehler RC, et al. Effect of epinephrine on cerebral and myocardial perfusion in an infant animal preparation of cardiopulmonary resuscitation. Circulation. 1986;73:809.)

The characteristics of chest geometry of animals may relate to that in humans. Body weight, surface area, chest circumference, and diameter did not correlate with the magnitude of aortic pressure produced during CPR in a study of nine adults already declared dead.[62] A direct comparison of adult and pediatric human CPR has not been performed. The higher intravascular pressures and organ blood flow during CPR in infants compared with adults may result from more effective transmission of the force of chest compression because of the higher compliance and greater deformability of the infant chest.

Effects of Cardiopulmonary Resuscitation on Intracranial Pressure

When chest compressions are applied, the increase in intrathoracic pressure is transmitted through the venous system of the head and neck to the intracranial vault, resulting in an increased intracranial pressure (ICP). Pressure is transmitted via the paravertebral veins and the cerebrospinal fluid during CPR in dogs.[64] Large swings in ICP corresponding to chest compressions occur in children undergoing CPR (Fig. 41.8).[65] This transmission of intrathoracic pressure to the intracranial contents accounts for the low cerebral perfusion pressure by increasing the

downstream pressure and cerebral blood flow during closed-chest CPR. However, in a porcine model of CPR with an impedance threshold device, it was found that CPR done in a reverse Trendelenberg position (head up at 30°) reduced ICP and improved cerebral perfusion, likely because gravity improved venous drainage and thus reduced impedance to forward flow.[58]

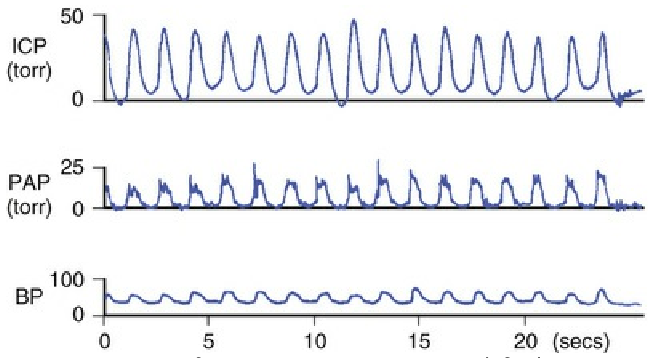

FIG. 41.8 Relationship of intracranial pressure *(ICP)*, pulmonary artery pressure *(PAP)*, and arterial blood pressure *(BP)* during closed-chest cardiac massage. Note that each chest compression is accompanied not only by a rise in arterial and pulmonary artery pressure but also by a sharp rise in intracranial pressure. (From Rogers MC, Nugent SK, Stidham GL. Effects of closed-chest cardiac massage on intracranial pressure. Crit Care Med. 1979;7:454.)

The relationship of ICP to intrathoracic pressure during CPR is linear. In dogs receiving conventional CPR, ICP increased by one-third of the rise of intrathoracic pressure in a range from 10 to 90 mm Hg.[64] However, some modes of CPR change the intrathoracic to ICP relationship. In dogs, abdominal binding increases the transmission of pressure to the intracranial space to one half of the rise of intrathoracic pressure.[66] SCV-CPR, a mode of CPR designed to generate higher intrathoracic pressure, is similar to conventional CPR in its transmission of pressure to the cranium. Open-chest CPR decreases the transmission of pressure and improves cerebral perfusion pressure compared with conventional CPR. Thus increasing intrathoracic pressure may decrease cerebral blood flow because of the increase in downstream pressure, the ICP.

In this regard, ACD-CPR and ACD-ITV-CPR may have an advantage over conventional CPR. These techniques are designed to reduce intrathoracic pressure. Lindner et al. showed in a porcine model that cerebral perfusion is increased with ACD-ITV-CPR compared with standard CPR.[67] Using an adult porcine model of hypothermic VF arrest, the same group demonstrated by microdialysis techniques improved lactate/pyruvate ratios and reduced glucose accumulation in the ACD-ITV group compared with standard CPR.[68] In a pediatric porcine model of resuscitation, Voelckel et al. found that ACD-CPR with ITV provided superior cerebral blood flow compared with standard CPR.[69]

Newer Cardiopulmonary Resuscitation Techniques

Simultaneous Compression Ventilation Cardiopulmonary Resuscitation

SCV-CPR is a technique designed to increase blood flow during conventional CPR by increasing the thoracic pump mechanism contribution to blood flow. Delivering a breath simultaneously with every compression, instead of after every fifth compression, increases intrathoracic pressure and augments blood flow produced by closed-chest CPR.

Experimental studies have shown that SCV-CPR increases carotid blood flow compared with conventional CPR alone.[70] Subsequent studies confirmed physiologic advantages of SCV-CPR in canine models.[31] However, in infant piglets and small dogs, SCV-CPR offered no advantage over conventional CPR.[60,62] In these small animals, the compliance and geometry of the chest may allow more direct cardiac compression. Thus higher intrathoracic pressure may be achieved with conventional CPR alone.[57,61] Coronary perfusion pressure (CPP) was either only minimally increased or even decreased in humans during SCV-CPR compared with conventional CPR. Survival was significantly worse in both animals and humans who received SCV-CPR compared with conventional CPR.[71,72] No study has shown an increased survival rate with this technique of CPR.

Interposed Abdominal Compression Cardiopulmonary Resuscitation

IAC-CPR is the delivery of an abdominal compression during the relaxation phase of chest compression. An extensive review by Babbs has been published.[73] IAC-CPR may augment conventional CPR in several ways. First, IAC-CPR may return venous blood to the chest during chest relaxation.[74,75] Second, IAC-CPR increases intrathoracic pressure and augments the duty cycle of chest compression.[74,76] Third, IAC-CPR may compress the aorta and return blood retrograde to the carotid or coronary arteries.[75] IAC-CPR is an attractive alternative to some of the newer techniques of CPR because it requires no additional equipment for implementation; however, it does require training and manpower.

In animal experiments, cardiac output and cerebral and coronary blood flow were improved when comparing IAC-CPR with conventional CPR but not in an infant model.[77,78] Additionally, in one animal experiment with newborn piglets examining chest compressions with manual sustained inflations of 30 cm H_20 versus current standard of care, ROSC was improved with better hemodynamic recovery in the group receiving sustained inflations.[79] Initial human studies also demonstrated an increase in aortic pressure and CPP during IAC-CPR compared with conventional CPR.[80] Four randomized controlled trials have compared IAC-CPR with standard CPR. The first trial reported in 1985 by Mateer et al. was the largest and included 291 patients.[81] IAC-CPR was applied in the field by paramedics until ambulance transport. No differences in mortality were found. The later trials involved a total of 279 hospitalized patients.[82-84] The results from these trials are more positive, and a meta-analysis of these studies found an increased likelihood of return of spontaneous circulation (ROSC) and intact survival to discharge with IAC-CPR versus standard CPR.[73,85] Although no intraabdominal trauma was detected in any of the 426 patients in these trials, one pediatric case report demonstrated direct

pancreatic injury. Alternative techniques for abdominal hand position were studied in adult swine.[86,87] A stacked hand position similar to the usual position for chest compression over the abdominal aorta was compared with a diffuse hand position in which the hands were placed on the abdomen separately. This study demonstrated a significant increase in aortic diastolic pressure compared with standard CPR. However, CPP was not augmented because the right atrial diastolic pressure was also elevated. Stacked hand position was found to produce a CPP equivalent to standard CPR. Diffuse hand position, however, was associated with decreased CPP, so if the technique is applied, this hand position should be avoided. Application of IAC-CPR is limited by the need for training and additional manpower. Although it has not been studied in a pediatric group, with skilled personnel available, IAC-CPR should be considered for use with inpatient arrests.

Active Compression-Decompression Cardiopulmonary Resuscitation and Impedance Threshold Valve Interposition

ACD-CPR uses a negative pressure "pull" on the thorax during the release phase of chest compression using a handheld suction device (Fig. 41.9).[88] This technique improves vascular pressures and minute ventilation during CPR in animals and humans.[67,88-90] The mechanism of benefit of this technique is attributed to enhancement of venous return by the negative intrathoracic pressure generated during the decompression phase; in addition, it reverses the chest wall deformation that accompanies standard CPR.[91] Preliminary results in adults were promising, and a large multi-institutional study of ACD-CPR completed in Europe found that ACD-CPR was superior to standard CPR.[90,92,93] In this study, a total of 750 patients were randomly assigned to receive standard CPR or ACD-CPR. In the experimental group, 5% survived to 1 year (12 patients with intact neurologic status) versus 2% (three patients with intact neurologic status) in the standard group.[94] However, a number of other trials have not shown a difference between standard CPR and ACD-CPR. A Cochrane Database Systematic Review concluded there was no consistent benefit from use of this technique.[95] The effectiveness of ACD-CPR appears to be relatively site specific. Explanations for this variability have focused on the effectiveness of training for providers and intersite variation of on-scene advanced life support techniques.[91] Use of ACD-CPR requires significantly more physical effort than conventional CPR, and this requirement may have influenced outcome.[96] No device is currently cleared for clinical use in the United States at this time.

FIG. 41.9 (A) and (B) are properly placed. Device for performing active compression-decompression cardiopulmonary resuscitation. (B) The upper part is a handle and the lower part is a suction cup. (Courtesy AMBU Corporation. From Halperin H. New devices for generating blood flow during cardiopulmonary resuscitation. Curr Opin Crit Care. 2004;10:188-192.)

Use of an inspiratory threshold valve has been evaluated in attempts to improve the outcome with ACD-CPR.[94,97] This technique involves the use of a valve placed between the ventilating bag and the airway, which is designed to close when the tracheal pressure falls below atmospheric pressure, enhancing the development of negative intrathoracic pressure during ACD-CPR (Figs. 41.10 and 41.11). Animal studies, including a young porcine model, showed improved organ perfusion, and brain microdialysis studies demonstrated decreased lactate accumulation and improved glucose utilization.[68,69,98,99] In a small series of patients, diastolic pressure was raised along with CPP and end-tidal CO_2 ($EtCO_2$) release.[100] These studies led to an inclusion of the technique as an acceptable alternative to standard CPR in the 2000 AHA guidelines and subsequent revised guidelines.[47,49] Plaisance et al. reported on a series of 400 patients randomly assigned to ACD-CPR with ITV or sham ITV. Survival at 24 hours was significantly improved in patients assigned to ACD-CPR.[94,100] There was a nonsignificant trend toward improved neurologic survival, with 6 of 10 discharged patients having intact survival compared with 1 of 8 discharged survivors in the sham ITV group. In two randomized control studies by Wolcke et al.[100a] and Plaisance et al. of 610 adults in cardiac arrest in the out-of-hospital setting, use of ACD-CPR plus the ITD was associated with improved ROSC and 24-hour survival rates when compared with CPR alone.[100] The addition of the ITD was associated with improved hemodynamics during standard CPR in one clinical study.[101] The ultimate role of this technique, which requires specialized equipment and significant resuscitator training, remains to be determined.[94,102]

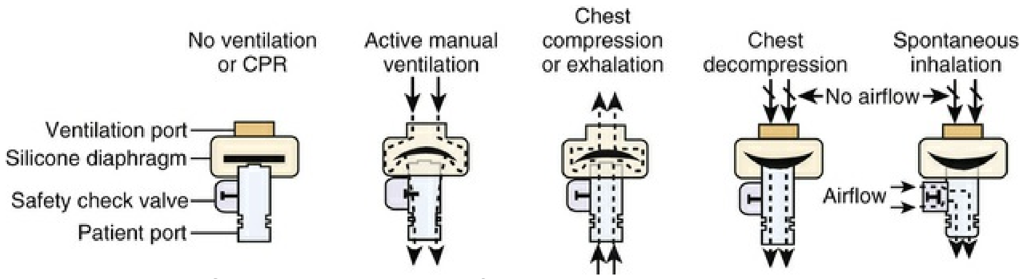

FIG. 41.10 Schematic diagram of impedance threshold valve. During a positive pressure ventilation the valve is open and gas flows. During chest compression or exhalation air moves freely through the valve. During chest decompression airflow is impeded by the valve decreasing intrathoracic pressure. During spontaneous ventilation the check valve opens allowing gas flow. *CPR,* cardiopulmonary resuscitation. (From Lurie KG, Barnes TA, Zielinski TM, et al. Evaluation of a prototypic inspiratory impedance valve designed to enhance the efficiency of cardiopulmonary resuscitation. Resp Care. 2003;48:52-57.)

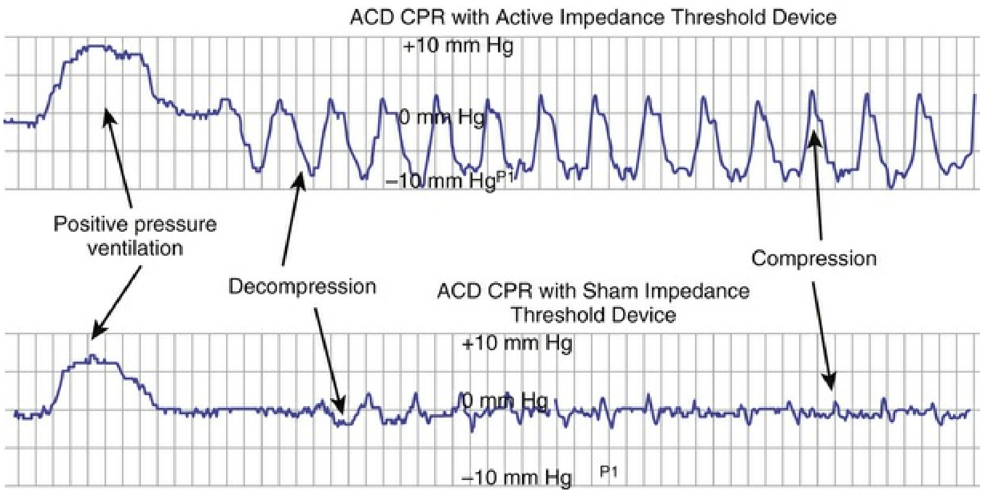

FIG. 41.11 Example of intratracheal pressures, a surrogate for intrathoracic pressures, in a patient undergoing cardiopulmonary resuscitation *(CPR)* with an automated compression device *(ACD)* with and without an impedance threshold device attached to a facemask. CPR was delivered at 100 compression/decompression cycles/min with a synchronized compression/ventilation ratio of 15 : 2. Note the absence of significant decreases in intratracheal pressures with a sham device. With the active impedance threshold device, wide fluctuations in intratracheal pressure are seen with each compression and decompression. (Courtesy M. Lurie, M.D., and Advanced Circulatory Systems, Inc.)

Vest Cardiopulmonary Resuscitation

Vest CPR uses an inflatable bladder resembling a blood pressure cuff that is wrapped circumferentially around the chest with phased inflation to increase intrathoracic pressure. Because chest dimensions are changed minimally, direct cardiac compression is unlikely. In addition, the even distribution of the force of compression over the entire chest wall decreases the likelihood of trauma to the

skeletal chest wall and its thoracic contents.

Improvement of cerebral and myocardial blood flows and survival with vest CPR compared with conventional CPR was seen in dogs.[27,103-106] In piglets, a 3% permanent chest deformation was seen after 50 minutes of vest CPR, compared with an almost 30% deformation produced during an equivalent period of conventional CPR.[61,63] In a human study, vest CPR increased aortic systolic pressure but had little effect on aortic diastolic pressure compared with conventional CPR.[107] Despite its late application, vest CPR improved the hemodynamics and the rate of ROSC in adult patients in another study.[108] Evidence from a case control study of 162 adults documented improvement in survival to the emergency department when vest CPR was administered by adequately trained personnel to patients in cardiac arrest in the out-of-hospital setting.[109] The lack of metallic parts has allowed vest CPR to be used experimentally during nuclear magnetic resonance spectroscopy to study brain intracellular pH.[110] The vest also has been used as an external cardiac assist device in nonarrested dogs with heart failure.[111] Clinically, the use of vest CPR depends on sophisticated equipment and remains experimental at this time.

Abdominal Binding

Abdominal binders and military antishock trousers have been used to augment closed-chest CPR. Both methods apply continuous compression circumferentially below the diaphragm. Three mechanisms have been proposed for augmentation of CPR by these binders. First, binding the abdomen decreases the compliance of the diaphragm and raises intrathoracic pressure. Second, blood may be moved out of the intrathoracic structures to increase circulating blood volume. Third, applying pressure to the subdiaphragmatic vasculature and increasing its resistance may increase suprathoracic blood flow. These effects increase aortic pressure and carotid blood flow in both animals and humans.[31,112] Unfortunately, as aortic pressure increases, the downstream component of CPP, namely, right atrial pressure, increases to an even greater extent, resulting in decreased CPP and myocardial blood flow.[28] These techniques also lower the cerebral perfusion pressure by enhanced transmission of intrathoracic pressure to the intracranial vault, which raises ICP (the downstream component of cerebral perfusion pressure). Clinical studies have failed to show an increased survival when an abdominal binder or military antishock trouser suit was used to augment CPR.

Open-Chest Cardiopulmonary Resuscitation

Use of open-chest cardiac massage has generally been replaced by closed-chest CPR. Compared with closed-chest CPR, open-chest CPR generates higher cardiac output and vital organ blood flow.[113] During open-chest CPR there is less elevation of intrathoracic, right atrial, and intracranial pressure, resulting in higher coronary and cerebral perfusion pressure and higher myocardial and cerebral blood flow.[114]

Open-chest CPR is not a technique that can be applied by most health care personnel. It can be used in the operating room, ICU, or emergency department equipped with the necessary surgical and technical equipment and personnel. It is easily used in the operating room or ICU after cardiac surgery when the open chest can be easily accessed. Open-chest CPR is indicated for cardiac arrest resulting from

cardiac tamponade, hypothermia, critical aortic stenosis, and ruptured aortic aneurysm. Other indications include cardiac arrest resulting from penetrating or crushed chest wall abnormalities that make closed-chest CPR impossible or ineffective.[115] Open-chest CPR is indicated for select patients when closed-chest CPR has failed, although exactly which patients should receive this method of resuscitation under this condition is controversial. When initiated early after failure of closed-chest CPR, open-chest CPR may improve outcome.[116] When performed after 15 minutes of closed-chest CPR, open-chest CPR significantly improves CPP and the rate of successful resuscitation.[117]

Cardiopulmonary Bypass

Because of the low rate of survival after prolonged CPR, more aggressive methods have been suggested to improve its success: cardiopulmonary bypass (CPB) and extracorporeal membrane oxygenation CPR (E-CPR).[118]

CPB is one of the most effective ways to restore circulation after cardiac arrest. Animal studies show that CPB increases survival at 72 hours, increases recovery of consciousness, and preserves the myocardium better than does conventional CPR.[119] In dogs, CPB resulted in better neurologic outcome than conventional CPR after a 4-minute ischemic period; however, neurologic outcome was dismal in both groups when the ischemic period lasted 12 minutes.[119] Some 90% of dogs survived 24 hours after 15 to 20 minutes of cardiac arrest, but only 10% survived when the arrest time was prolonged to 30 minutes when CPB was used for stabilization during defibrillation.[120] CPB decreased myocardial infarct size in a model involving coronary artery occlusion compared with conventional CPR.[121] In all animal models, CPB improves the success of resuscitation compared with conventional CPR.

Human experience with CPB for cardiac arrest outside the operating room is growing. In the first major series of pediatric patients undergoing E-CPR, reported by Morris et al., 64 children underwent 66 extracorporeal membrane oxygenation (ECMO) runs initiated during active resuscitation with chest compressions or internal cardiac massage.[122] Of these patients, 33 (50%) were decannulated and survived for more than 24 hours, 21 (33%) survived to hospital discharge, and 16 (26%) reportedly had no major changes in neurologic outcome. The average duration of CPR before cannulation in the survivors was 50 minutes. Of the six surviving children who required more than 60 minutes of CPR before ECMO, three had no apparent change in neurologic status. During the same period, 73 children underwent standard CPR; 10 received CPR for more than 30 minutes, with no survivors. Duncan et al. reported a series of 18 pediatric cardiac surgical patients at the Boston Children's Hospital who received ECMO during active chest compressions.[123] Of the first seven patients, only 29% survived. This led to the development of a rapid ECMO deployment strategy in which an ECMO pump is kept saline-primed in the ICU at all times, allowing initiation of extracorporeal support within 15 minutes. Precannulation support times dropped from an average of 90 minutes but still remained high at an average of 50 minutes. Of the remaining 11 patients, 10 were decannulated successfully, with 6 long-term survivors, 5 of whom were in New York Heart Association class I. This rapid deployment strategy likely will become more commonplace in large pediatric centers.

Many subsequent pediatric and adult studies have shown both the feasibility and

varied success of E-CPR. Clear indications for its use include witnessed arrest in a biventricular circulation, and whereas contraindications include inability to provide effective CPR, there is uncertainty for the role of E-CPR in prolonged conventional resuscitation, because there are no guidelines on when to initiate it or which patient population it would be best suited for. This lack of criteria may explain the wide range of success of E-CPR, with survival ranging between 33% and 100%.[124]

Under the 2015 AHA guidelines, centers should consider ECMO CPR for in-hospital cardiac arrest refractory to standard resuscitation attempts if the condition leading to cardiac arrest is reversible or amenable to heart transplantation, if excellent conventional CPR has been performed after no more than several minutes of no-flow cardiac arrest, and if the institution is able to rapidly perform ECMO. Long-term survival has been reported even after more than 150 minutes of CPR in selected patients.[49]

Data are emerging involving the role of ECMO in persons with refractory ventricular fibrillation.[125] These data have solely been in the form of case reports but may represent a future direction for the care of patients with VF. In 2006, Samson et al. reported successful treatment of in-hospital VF in children with ECMO after cardiac arrest who had an initial rhythm of VF and immediate initiation of CPR.[126]

CPB and ECMO require a great deal of technical support and sophistication. In units with preprimed circuits on standby, CPB can be implemented quickly and with moderate success in a population of children who would otherwise almost certainly die. The success with some patients undergoing very long CPR times followed by ECMO use is encouraging and suggests the possibility of reversible myocardial injury as a cause of resuscitation failure in a subset of patients. Overall, ECMO is unlikely to have a major impact on pediatric outcome because of its limited availability.

Transcutaneous Cardiac Pacing

Transcutaneous cardiac pacing (TCP) is used as a method for noninvasive pacing of the ventricles for a relatively short period. Emergency cardiac pacing is successful in resuscitation only if it is initiated soon after the onset of arrest. In the absence of in situ pacing wires or an indwelling transvenous or esophageal pacing catheter, TCP is the preferred method for temporary electrical cardiac pacing. Since 1992, the AHA advanced cardiovascular life support (ACLS) guidelines have recommended the early use of an external pacemaker in patients with symptomatic bradycardia or asystole.[127]

Since Zoll established TCP in 1952 as a clinically useful method of pacing adult patients during ventricular standstill (Stokes-Adams attacks) and bradycardia-associated hypotension, numerous anecdotal reports have supported its use for bradycardic or asystolic arrests.[128] Zoll et al. reported successful in-hospital resuscitation of 12 of 16 patients with hypotensive bradycardia or asystole if TCP was initiated within 5 minutes of the arrest.[129] In contrast, if TCP was started between 5 and 30 minutes after the arrest, only 8 of 44 patients with either of these rhythms could be resuscitated.[129] In two controlled clinical trials of prehospital TCP, no differences in the survival rate or success of resuscitation were observed in paced and nonpaced patients who had asystole or PEA.[130,131] In patients with symptomatic bradycardia, TCP improved resuscitation and the survival rate.[132]

To date the efficacy of TCP in resuscitation of children has not been studied. Beland et al. showed that effective TCP could be achieved in hemodynamically stable children during induction of anesthesia for heart surgery.[133] They were successful in 53 of 56 pacing trials, and the patients experienced no complications.[131,133]

TCP is indicated for patients whose primary problem is impulse formation or conduction and who have preserved myocardial function. TCP is most effective in patients with sinus bradycardia or high-grade atrioventricular block with slow ventricular response who also have a stroke volume sufficient to generate a pulse. TCP is not indicated for patients in prolonged arrest because in this situation TCP usually results in electrical but not mechanical cardiac capture, and its use may delay or interfere with other resuscitative efforts.

To set up pacing, one electrode is placed anteriorly at the left sternal border and the other posteriorly just below the left scapula. Smaller electrodes are available for infants and children; adult-sized electrodes can be used in children weighing more than 15 kg.[133] Electrocardiographic leads should be connected to the pacemaker, the demand or asynchronous mode selected, and an age-appropriate heart rate used. The stimulus output should be set at zero when the pacemaker is turned on and then increased gradually until electrical capture is seen on the monitor. The output required for a hemodynamically unstable rhythm is higher than that for a stable rhythm in children in whom the mean stimulus required for capture was between 52 and 65 mA. After electrical capture is achieved, one must ascertain whether an effective arterial pulse is generated. If pulses are not adequate, other resuscitative efforts should be used.

The most serious complication of TCP is induction of a ventricular arrhythmia.[134] Fortunately, this complication is rare and may be prevented by pacing only in the demand mode. Mild transient erythema beneath the electrodes is common. Skeletal muscle contraction can be minimized by using large electrodes, a 40-ms pulse duration, and the smallest stimulus required for capture. Sedatives or analgesics may be necessary in the patient who is awake. If defibrillation or cardioversion is necessary, one must allow a distance of 2 to 3 cm between the electrode and paddles to prevent arcing of the current.

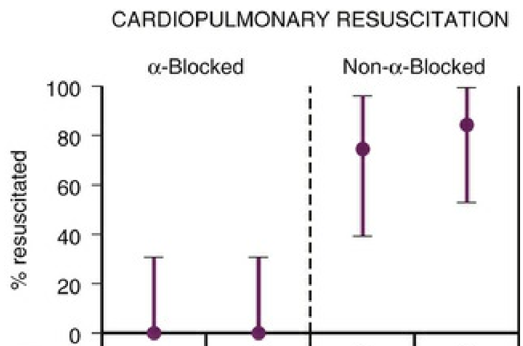
Pharmacology

Adrenergic Agonists

In 1963, only 3 years after the original description of closed-chest CPR, Pearson and Redding described the use of adrenergic agonists for resuscitation.[135] They subsequently showed that early administration of epinephrine in a canine model of cardiac arrest improved the success rate of CPR. They also demonstrated that the increase in aortic diastolic pressure by administration of α-adrenergic agonists was responsible for the improved success of resuscitation. They theorized that vasopressors such as epinephrine were of value because the drug increased peripheral vascular tone, not because of a direct effect on the heart.[136]

Yakaitis et al. investigated the relative importance of α- and β-adrenergic agonist actions during resuscitation.[137] Only 27% of dogs that received a pure β-adrenergic receptor agonist along with an α-adrenergic antagonist were resuscitated

successfully, compared with all of the dogs that received a pure α-adrenergic agonist and a β-adrenergic antagonist (Fig. 41.12). Later studies reconfirmed this finding.[138] Michael et al. demonstrated that the α-adrenergic effects of epinephrine result in intense vasoconstriction of the resistance vessels of all organs of the body, except those supplying the heart and brain.[42] Because of the widespread vasoconstriction in nonvital organs, adequate perfusion pressure and thus blood flow to the heart and brain can be achieved despite the fact that cardiac output is very low during CPR (Fig. 41.13).[61]



Group	A	C	B	D
Observed frequency	0	0	75	87.5
90% interval	0–31	0–31	40–95	53–99

FIG. 41.12 Beneficial effect of α-adrenergic activity on resuscitation. Animals in group A received phenoxybenzamine; group B received propranolol; group C received phenoxybenzamine and propranolol; and group D received no drug. The 90% confidence intervals are reported for the sample size and observed resuscitation success. The lack of overlap between the α- and non–α-blocked groups indicates a significant benefit (p ≤.01) during resuscitation when α-adrenergic activity is intact. (From Yakaitis RW, Otto CW, Blitt CD. Relative importance of alpha and beta adrenergic receptors during resuscitation. Crit Care Med. 1979;7:293.)

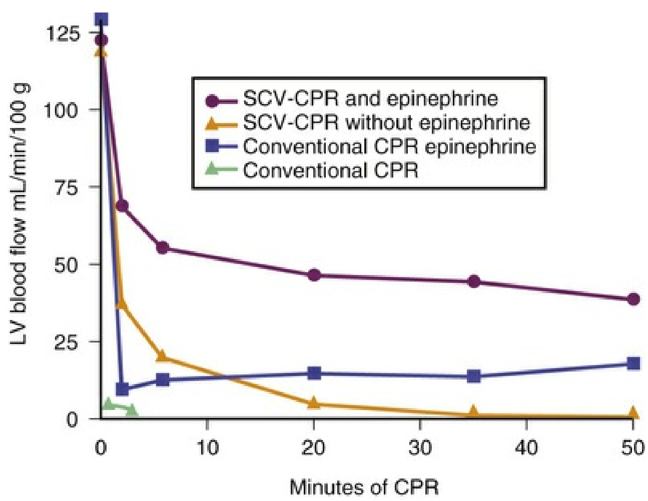


FIG. 41.13 Left ventricular *(LV)* blood flow before arrest and during four types of cardiopulmonary resuscitation *(CPR).* Note the rapid falloff of LV

blood flow when epinephrine is not used. *SCV-CPR*, simultaneous compression ventilation CPR. (From Michael JR, Guerci AD, Koehler RC, et al. Mechanisms by which epinephrine augments cerebral and myocardial perfusion during cardiopulmonary resuscitation in dogs. Circulation. 1984;69:822.)

The increase in aortic diastolic pressure associated with epinephrine administration during CPR is critical for maintaining coronary blood flow and enhancing the success of resuscitation. Even though the contractile state of the myocardium is increased by use of β-adrenergic agonists in the spontaneously beating heart, during CPR, β-adrenergic agonists actually may decrease myocardial blood flow by increasing intramyocardial wall pressure and vascular resistance. This decrease in myocardial blood flow could redistribute intramyocardial blood flow away from the subendocardium, increasing the likelihood of ischemic injury to this region.[139] Moreover, evidence indicates that left ventricular end-diastolic pressure (LVEDP) rises with epinephrine use, reducing the overall impact of the vasoconstrictor effects of epinephrine on CPP. Tang et al. showed elevated LVEDP and decreased measures of diastolic performance in epinephrine-resuscitated rats after induced VF compared with phenylephrine-resuscitated animals or epinephrine-resuscitated animals who also received a β-blocker.[140] Similar data were found by McNamara, who used a rat pup model of asphyxial arrest.[141] LVEDP was increased and diastolic function indices decreased with epinephrine compared with either saline solution alone or epinephrine combined with verapamil. These data imply that excessive β-adrenergic effects prevent the intracellular calcium reuptake during diastole that is required for myocardial relaxation. By its inotropic and chronotropic effects, β-adrenergic stimulation increases myocardial oxygen demand, which, when superimposed on low coronary blood flow, increases the risk of ischemic injury. This combination of increased oxygen demand by β-adrenergic agonists and decreased oxygen supply may damage an already ischemic heart, raising the question of whether a pure α-adrenergic agonist would be better than epinephrine, which has significant β-adrenergic effects (Box 41.1).[142] The effects on energy utilization and oxygen supply not only have implications for the success of the initial resuscitation but also for the postresuscitation function of the myocardium.

Box 41.1

α-Adrenergic vs. β-Adrenergic Agonist Effects

α-Adrenergic Effects

- Vasoconstrict peripheral vessels
- Maintain aortic diastolic pressure
- Improve coronary blood flow
- *No* metabolic stimulatory effect

β-Adrenergic Effects

- Vasodilate peripheral vessels
- Decrease aortic diastolic pressure
- Increase cellular metabolic rate
- Positive inotrope
- Increase intensity of ventricular fibrillation
- Increase heart rate and/or dysrhythmias following resuscitation

A number of studies have attempted to settle this controversy and actually have shown that pure α-adrenergic agonists can be used in place of epinephrine during CPR. Phenylephrine and methoxamine are two pure α-adrenergic agonists that have been used in animal models of CPR with success equal to that of epinephrine.[61,137,139] More recently, vasopressin has been studied as a noncatecholamine vasoconstrictor in the management of patients who experience cardiac arrest.[17] This agent is discussed in the section on vasopressin. These agents cause peripheral vasoconstriction and increase aortic diastolic pressure, resulting in improved myocardial and cerebral blood flow. This effect results in a higher oxygen supply/demand ratio in the ischemic heart and, at least, a theoretical advantage over the combined α- and β-adrenergic agonist effects of epinephrine. These agonists, as well as vasopressors such as vasopressin, have been used successfully for resuscitation.[17,136,143] These drugs maintain blood flow to the heart during CPR as well as epinephrine does. In an animal model of VF cardiac arrest, a resuscitation rate of 75% was reported for both epinephrine- and phenylephrine-treated groups. In this study, the ratio of endocardial to epicardial blood flow was lower in the group treated with epinephrine, suggesting the presence of subendocardial ischemia.[61] However, studies of this kind are difficult to interpret because of the inability to measure the degree of α-receptor activation by the different vasopressors. The higher subendocardial blood flow in the phenylephrine group may have been the result of less α-receptor activation.[144-146] Moreover, some investigators have questioned the merits of using a pure α-adrenergic agonist during CPR. Although the inotropic and chronotropic effects of β-adrenergic agonists may have deleterious hemodynamic effects during CPR administered for VF, increases in both heart rate and contractility increase cardiac output when spontaneous coordinated ventricular contractions are achieved.

Cerebral blood flow during CPR, like coronary blood flow, depends on peripheral vasoconstriction and is enhanced by use of α-adrenergic agonists. This action produces selective vasoconstriction of noncerebral peripheral vessels to areas of the head and scalp without causing cerebral vasoconstriction.[61] As with myocardial blood flow, pure α-agonist agents are as effective as epinephrine in generating and sustaining cerebral blood flow during CPR in adult animal models and in infant models (Fig. 41.14).[61,143] No difference in neurologic deficits 24 hours after cardiac arrest was found between animals receiving either epinephrine or phenylephrine during CPR.[147]

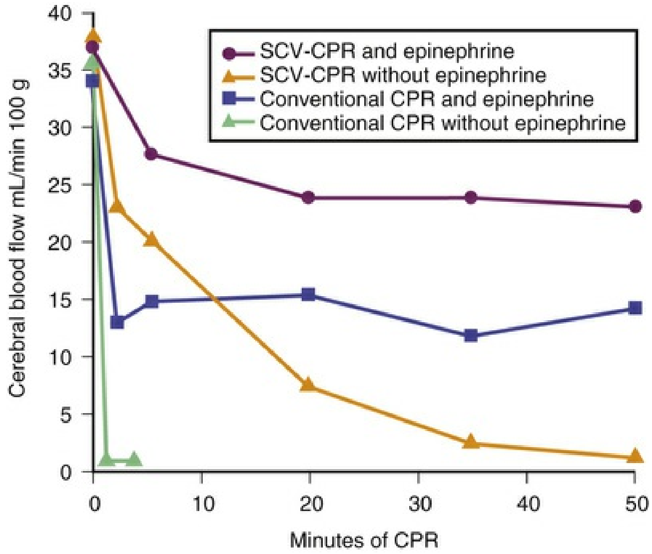

FIG. 41.14 Cerebral blood flow before arrest and during four types of 50 minutes of cardiopulmonary resuscitation *(CPR). SCV-CPR*, simultaneous compression ventilation CPR. (From Michael JR, Guerci AD, Koehler RC, et al. Mechanisms by which epinephrine augments cerebral and myocardial perfusion during cardiopulmonary resuscitation in dogs. Circulation. 1984;69:822.)

Analogous to the heart, β-adrenergic agonists could increase cerebral oxygen uptake if a sufficient amount of drug crosses the blood-brain barrier during or after resuscitation. In addition, adrenergic agonists may vasoconstrict or dilate cerebral vessels, depending on the balance between α- and β-adrenergic receptors. Epinephrine and phenylephrine had similar effects on cerebral blood flow and metabolism, maintaining normal cerebral oxygen uptake for 20 minutes of CPR in dogs. This finding implies that cerebral blood flow was high enough to maintain adequate cerebral metabolism and that β-receptor stimulation did not increase cerebral oxygen uptake, despite the fact that the combined effects of brain ischemia and CPR can increase the permeability of the blood-brain barrier to drugs used during CPR or when enzymatic barriers to vasopressors (eg, by monoamine oxidase) are overwhelmed during tissue hypoxia. Mechanical disruption of the barrier could occur during chest compressions by large fluctuations in cerebral venous and arterial pressures or as a result of hyperemia, the large increase in cerebral blood flow that occurs during the early reperfusion period when the cerebral vascular bed is maximally dilated following resuscitation, particularly if systemic hypertension occurs.[148] No blood-brain barrier permeability changes during CPR immediately after resuscitation or 4 hours after resuscitation were found in adult dogs.[148] However, after 8 minutes of cardiac arrest and 6 minutes of CPR in piglets, the blood-brain barrier was permeable to the small neutral amino acid α-aminoisobutyric acid 4 hours after cardiac arrest (Fig. 41.15).[149,150] The increase in permeability could be prevented by pre-arrest administration of conjugated superoxide dismutase and catalase, indicating a role of oxygen free radicals in the pathogenesis of this injury to the blood-brain barrier (Fig. 41.16).[151] These endothelial membrane changes frequently were associated with the presence of intravascular polymorphonuclear and monocytic leukocytes.[152] Whether leukocytes disrupt the blood-brain barrier by release of toxic substances, such as oxygen free radicals or proteases, or appear in the post-ischemic microvessels as an epiphenomenon of a

more important derangement is unknown (Fig. 41.17).

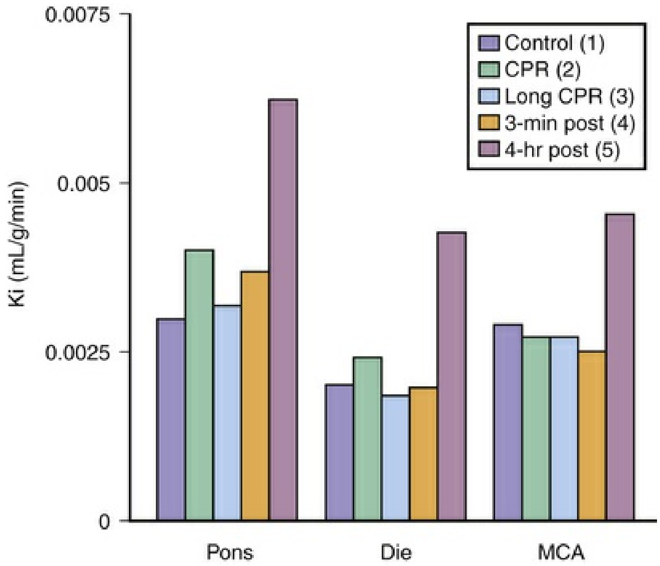

FIG. 41.15 Transfer coefficient *(K_i)* of α-aminoisobutyric acid for pons, diencephalon *(DIE),* and middle cerebral *(MCA)* artery regions. Control group; 8 minutes ischemia and 10 minutes cardiopulmonary resuscitation *(CPR);* 8 minutes ischemia and 40 minutes cardiopulmonary resuscitation; 3 minutes after resuscitation; 4 hours after resuscitation. Group 5 in each region *p <.05, different from group 1 by one-way analysis of variance and Dunnett test for all three regions. (From Schleien CL, Koehler RC, Schaffner DH, et al. Blood-brain barrier disruption after cardiopulmonary resuscitation in immature swine. Stroke. 1991;22:477.)

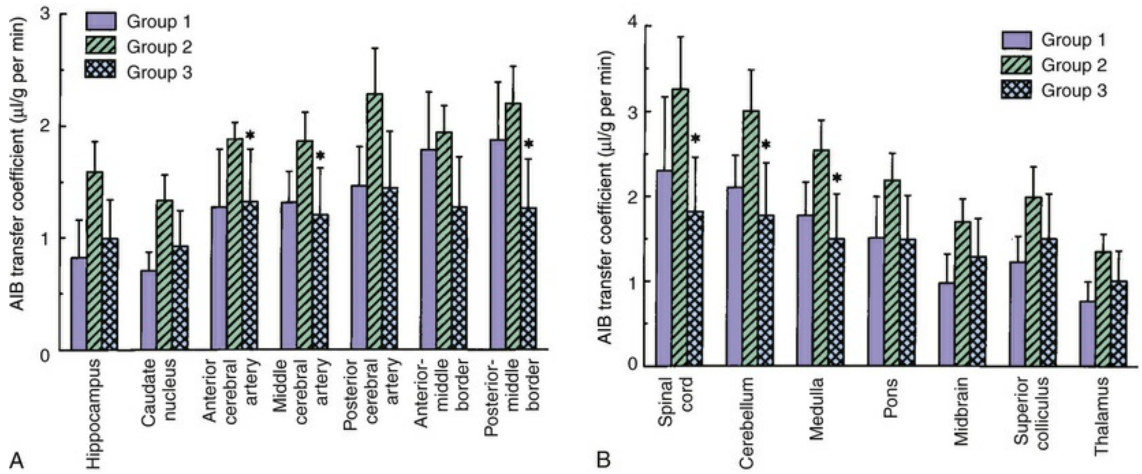

FIG. 41.16 (A) Bar graph showing transfer coefficient of α-aminoisobutyric acid *(AIB)* from plasma to brain in hippocampus, caudate nucleus, and primary supply and border regions of cerebral arteries in nonischemic time controls (group 1; *n* = 5), ischemia group treated with polyethylene glycol *(PEG)* (group 2; *n* = 8), and ischemia group treated with PEG-superoxide dismutase and PEG-catalase (group 3; *n* = 8). Error bars represent standard error of the mean *(SEM).* *p <.05 between groups 2 and 3 by Mann-Whitney U test. (B) Transfer coefficient of AIB from

plasma to brain in caudal brain regions in nonischemic time controls (group 1; $n = 5$), ischemia group treated with PEG (group 2; $n = 8$), and ischemia group treated with PEG-superoxide dismutase and PEG-catalase (group 3; $n = 8$). Error bars represent SEM. *$p < .05$ between groups 2 and 3 by Mann-Whitney U test. (From Schleien CL, Eberle B, Schaffner DH, et al. Reduced blood-brain barrier permeability after cardiac arrest by conjugated superoxide dismutase and catalase in piglets. Stroke. 1994;25:1830.)

FIG. 41.17 Transmission electron micrograph of an infant piglet brain 4 hours after 8 minutes of cardiac arrest and 6 minutes of cardiopulmonary resuscitation (magnification ×5000). An intravascular leukocyte, which has the morphologic features of a monocyte, is adherent to the endothelial surface of a venule and appears to be occluding the lumen. The luminal surface of the endothelial cell contains membrane blebs and discontinuities. (From Caceres MJ, Schleien CL, Kuluz JW, et al. Early endothelial damage and leukocyte accumulation in piglet brains following cardiac arrest. Acta Neuropathol. 1995;90:582.)

Vasopressin

The role of vasopressin as a noncatecholamine vasoconstrictor in the management of patients who experience cardiac arrest has received a great deal of interest. Work by Lindner in Europe and Landry in the United States during the past 2 decades had established sufficient evidence of efficacy for its use to be included in the 2010 AHA Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care.[118,153] However, subsequent adult studies comparing standard dose epinephrine with vasopressin alone or in combination with standard dose epinephrine have showed that vasopressin offered no advantage in return of spontaneous circulation or survival to discharge,[154] and it has subsequently been removed from the 2015 AHA guidelines. However, increasing evidence indicates that vasopressin is a useful agent in the management of shock of multiple etiologies and therefore may have a role in postresuscitation management of the arrest victim.

Arginine vasopressin is a short peptide hormone secreted by the posterior pituitary gland in response to changes in tonicity and changes in effective intravascular volume, signaled primarily via baroreceptor unloading in the aorta.

Severe shock is the most potent stimulus to vasopressin secretion. Serum levels 20- to 200-fold higher than normal may be found immediately after cardiac arrest, as well as in other severe shock states. Despite these observations, lower than expected vasopressin levels have been found in some patients with profound shock, and patients dying of cardiac arrest have been found to have significantly lower vasopressin levels than do survivors.[155-159] The cause of lower than expected vasopressin levels in some patients is unclear. Observations in dogs suggest depletion of vasopressin stores as a potential mechanism. Dogs subjected to profound hemorrhagic shock have an early massive elevation of vasopressin levels immediately after the event, followed by a depression of levels below that expected within 1 hour of the insult. Severe depletion of vasopressin stores from the posterior hypophysis was noted in these animals.[160] These animals developed a catecholamine-refractory vasodilatory shock that responded dramatically to low doses of vasopressin.[161] These observations have led to an exploration of the use of vasopressin in both cardiac arrest and shock states.

Vasopressin is an extremely potent vasoconstrictor. Its effects on vascular tone are primarily mediated through interaction with a specific G protein–coupled receptor referred to as the $V1_a$ receptor, which is distributed widely throughout vascular beds.[159] Of note, the $V1_a$ receptor is linked to the same second messenger system as the α-adrenergic receptor that mediates vasoconstriction through an alteration of intracellular calcium levels. However, in the pulmonary circulation, vasopressin activation of V1 receptors mediates the release of nitric oxide and causes pulmonary vasodilation. Vasopressin also interacts with its V_2 receptor, which regulates aquaporin expression on the renal collecting duct epithelium. Stimulation of the V_2 receptor occurs at substantially lower levels than those required to activate the $V1_a$ receptor.

Vasopressin use during resuscitation has been studied in animals and humans. In an adult porcine model of VF, vasopressin at a dose of 0.8 μg/kg was found to be superior to the maximally effective dose of epinephrine 200 μg/kg in restoring left ventricular myocardial blood flow, increasing diastolic CPP and total cerebral blood flow, as well as rates of ROSC.[141] Moreover, the duration of the effect was sustained for 4 minutes compared with 1.5 minutes for epinephrine.[17] Adverse effects noted in the postresuscitation phase included decreased renal and adrenal blood flow and reduced cardiac output.[162,163]

In a pediatric porcine model of cardiac arrest, vasopressin at a dose of 0.8 μg/kg was not as effective as epinephrine, 200 μg/kg, in restoring LV myocardial blood flow or achieving ROSC.[164] Only one of six animals achieved ROSC compared with six of six in the epinephrine group. A combination group that received both epinephrine, 45 μg/kg, and vasopressin, 0.8 μg/kg, fared better (ROSC in four of six animals). Possible explanations for the difference between adult and juvenile animals include different dose-response curves for the two drugs, failure of maturation of vasopressin receptors, a different distribution of vasopressin receptors than seen in adults, or the different experimental model.

In an initial small randomized clinical trial of vasopressin compared with epinephrine for refractory VF, the rate of achieving ROSC was higher in the vasopressin group.[165] These findings led to the inclusion of vasopressin in the adult guidelines. A large multicenter randomized trial of vasopressin for cardiac arrest in

adults has been reported.[166] More than 1200 patients were randomly assigned in the field to receive two doses of either 40 international units (IU) of vasopressin or 1 mg of epinephrine followed by additional treatment with epinephrine, if necessary. Vasopressin was equivalent to epinephrine in achieving survival to both hospital admission and discharge in patients with either PEA or VF. In patients with asystole, vasopressin was superior to epinephrine in achieving both survival to admission and discharge, although intact neurologic outcome was not improved. In patients in whom ROSC was not achieved after two doses of medication, a third dose of medication such as epinephrine could be added at the resuscitating physician's discretion. In the group receiving a third dose of medication such as epinephrine, survival was greater in the vasopressin group. In a study of 200 patients with in-hospital cardiac arrest, patients were randomly assigned to receive either 1 mg of epinephrine or 40 units of vasopressin. Again, no statistical difference in survival to 1 hour or to hospital discharge was found between groups or subgroups.[167] The results of these studies led to the classification of evidence for vasopressin for use in adults as indeterminate in the 2010 AHA guidelines.[118] Subsequently, a meta-analysis of 10 randomized trials including a total of 6120 adult patients showed that the use of vasopressin was neither beneficial nor harmful in an unselected patient population in terms of ROSC, survival to hospital admission, survival to discharge, or favorable neurologic outcome. However, chance of ROSC was significantly higher in in-hospital cardiac arrest patients when vasopressin was used.[168] The published experience with vasopressin in children who experience cardiac arrest is limited. The first case series of vasopressin use in CPR reported the outcome of four children with six prolonged refractory cardiac arrests that were unresponsive to standard resuscitation efforts.[169] Each child received one or more bolus doses of vasopressin (0.4 μg/kg) as rescue therapy. In all children, the initial rhythm was a form of PEA that deteriorated to asystole in four of six events. Three children had ROSC for more than 60 minutes, including one child with asystole. Two children survived for more than 24 hours and one survived to hospital discharge. A second retrospective case series of pediatric cardiac arrests unresponsive to epinephrine found that ROSC was achieved in 6 of 8 episodes that were treated with terlipressin, a long-acting synthetic analog of vasopressin, at a dose of 15 to 20 μg/kg. Four of those patients survived without neurologic sequelae.[170] A review of a national registry of in-hospital CPR showed that patients who received vasopressin had a lower incidence of ROSC greater than 20 minutes (22 [34%] of 64) than patients who did not receive the medication (675 [55%] of 1229).[171] The association of poor outcome with vasopressin persisted even with multivariate analysis with logistic regression to attempt to control for other factors that might affect ROSC. The effect of vasopressin in pediatric arrest that was refractory to an initial epinephrine dose was evaluated in a pilot study. Patients were given vasopressin after an initial dose of epinephrine and were compared with a retrospective matched cohort of patients who experienced cardiopulmonary arrest that required greater than two doses of a vasopressor, not including vasopressin. Ten patients were enrolled, and although there was an increased 24-hour survival, there was no difference in ROSC, survival to hospital discharge, or favorable neurologic status at discharge.[172]

The current evidence only examines the use of vasopressin as a potential alternative when standard therapies, such as epinephrine, fail to cause ROSC. Unfortunately, variables such as dosing, timing of vasopressin infusion, or pediatric

risk of mortality scores have not been controlled for in these studies. No double-blinded, randomized controlled studies have been performed, and thus no firm recommendations are available concerning the use of vasopressin for CPR in infants and children.

The current recommended dose of vasopressin for adults in cardiac arrest is 40 IU. No data comparing this dose to other doses are available, and concern exists regarding postresuscitation complications related to this dose. We have selected 0.5 μg/kg as the standard for cardiac arrest. Further data are necessary before more definitive dosing recommendations can be made.

Use of vasopressin in postresuscitation management may be considered. A relative vasopressin deficiency has been noted in a number of shock states, including hemorrhage, sepsis, and post-CPB, as well as in patients who have unsuccessful resuscitations. In these settings, shock may be refractory to catecholamines (norepinephrine doses of 2 to 4 μg/kg). These patients may respond to a vasopressin infusion, allowing the weaning of high-dose catecholamines. Although a role in the postresuscitation setting has not been demonstrated on the basis of the data related to refractory shock, consideration of the use of vasopressin for refractory hypotension may be appropriate.

Additionally, the additive effects of combination drug therapy for adults with cardiac arrest may be most beneficial. In a recent randomized, double-blind placebo control study investigating vasopressin plus epinephrine or saline placebo plus epinephrine with/without methylprednisolone, the group receiving combination therapy with vasopressin-epinephrine-methylprednisolone with CPR resulted in improved survival to hospital discharge with improved neurologic status.[173,174]

High-Dose Epinephrine

The physiologic responses of animals and humans to higher doses of epinephrine include higher cerebral blood flow, increased myocardial and submyocardial blood flow, improved oxygen delivery relative to oxygen consumption, and less depletion of myocardial adenosine triphosphate (ATP) stores with more rapid repletion of phosphocreatine.[145,175-179] Contrary results, with increased myocardial oxygen consumption and decreased myocardial blood flow, have been demonstrated during CPR following VF cardiac arrest.[40,43] In a piglet model, high-dose epinephrine (HDE) produced lower myocardial blood flow than achieved with standard-dose epinephrine (SDE).[171] In neonatal lambs following asphyxia-induced bradycardia, HDE resulted in higher heart rate but a lower stroke volume and cardiac output.[180]

Studies regarding survival of patients who were given HDE have been contradictory. In out-of-hospital patients who experienced cardiac arrest, HDE produced higher aortic diastolic pressure during CPR and increased the rate of ROSC compared with standard doses of epinephrine. Gonzalez et al. demonstrated a dose-dependent increase in aortic blood pressure by epinephrine in patients who failed to respond to prolonged resuscitative efforts.[181,182] Paradis et al.[183] showed that HDE increased aortic diastolic pressure and improved the rate of successful resuscitation in patients in whom ACLS protocols had failed. This group also reported on a series of 20 children treated with HDE and compared them with 20 historic control subjects consisting of children with cardiac arrest treated with SDE.[184] They reported that 14 of the children in the HDE group had ROSC, 8

survived to hospital discharge, and 3 were neurologically intact. There were no survivors in the SDE comparison group. Other centers have claimed that higher-than-standard doses of epinephrine during CPR in children improve the hemodynamics and increase the success of CPR; however, no one has provided any valid data that suggest that HDE improves survival beyond the immediate postresuscitation period.[94,183,185,186] On the basis of these studies, the 1992 AHA guidelines for pediatric advanced life support recommended HDE if an initial SDE failed to resuscitate the child.

Three large multicenter studies subsequently were published that dampened enthusiasm for the use of HDE. Stiell et al. studied 650 adult patients after cardiac arrests who were randomly assigned to receive either an SDE or HDE (7 mg) epinephrine protocol.[187] No differences were observed between the groups with regard to 1-hour survival (23% vs. 18%), rate of hospital discharge (5% vs. 3%), or neurologic outcome. Brown et al.[23] reported on 1280 adult patients who received either SDE (0.02 mg/kg) or HDE (0.2 mg/kg) after cardiac arrest. Again, no differences in ROSC, short-term survival, survival to hospital discharge, or neurologic outcome were observed between the two groups of patients. In a study of 816 adults, Callaham et al. reported a higher ROSC in the HDE group.[188] However, there were no differences in the rate of hospital discharge or ultimate survival of these patients. In addition to these studies, a specific pediatric animal study was published that failed to demonstrate a clear survival benefit for HDE, although the occurrence of ROSC appeared to be greater.[43] The 2000 AHA guidelines changed the recommendation for HDE to an option for second and subsequent doses of epinephrine.

More recently, a prospective, randomized, double-blind clinical trial of HDE in 68 pediatric inpatients was reported by Perondi et al.[14] ROSC for more than 20 minutes was achieved in 15 of 34 patients who received HDE but in only 8 of 34 patients who received SDE ($p = .07$). However, survival to 24 hours occurred in only two of the HDE group versus seven of the SDE group ($p = .05$). In the group that experienced an asphyxial arrest, none of 12 treated with HDE was alive at 24 hours, whereas 7 of 18 patients in the SDE group survived. Four survived to hospital discharge, and two patients were neurologically normal.[14] This trial reinforces concerns that HDE may account for some of the adverse effects that occur after resuscitation and is the basis of the 2015 AHA guidelines' recommendation against the use of HDE during CPR.[150,189,190] As discussed previously, epinephrine can worsen myocardial ischemic injury secondary to increased oxygen demand and result in tachyarrhythmias, hypertension, pulmonary edema, hypoxemia, and cardiac arrest.[150,191] Use of a β-adrenergic antagonist during or after ROSC has been suggested to attenuate the adverse effects of epinephrine.[76,105,192] Epinephrine causes hypoxemia and an increase in alveolar dead space ventilation by redistributing pulmonary blood flow.[193,194] In one study, HDE (>15 mg) given to adults during CPR resulted in a lower cardiac index, systemic oxygen consumption, and oxygen delivery immediately after resuscitation.[180] A meta-analysis of epinephrine use in adult cardiac arrest showed no difference in survival to discharge or neurologic outcome when using high dose over standard dose.[195] Prolonged peripheral vasoconstriction by excessive doses of epinephrine may delay or impair reperfusion of systemic organs, particularly the kidneys and gastrointestinal tract.

Atropine

Atropine, a parasympatholytic agent, acts by blocking cholinergic stimulation of the muscarinic receptors of the heart, which usually results in an increase in the sinus rate and shortening of the atrioventricular node conduction time. Atropine may activate latent ectopic pacemakers. Atropine has little effect on systemic vascular resistance, myocardial perfusion pressure, or contractility.[177]

Atropine is indicated for treatment of asystole, PEA, bradycardia associated with hypotension, second- and third-degree heart block, and slow idioventricular rhythms. In children who present in cardiac arrest, sinus bradycardia and asystole are the most common initial rhythms, which make atropine useful as a first-line drug. Atropine is particularly effective in clinical conditions associated with excessive parasympathetic tone.

The recommended dose of atropine is 0.02 mg/kg, with a minimum dose of 0.15 mg and a maximum dose of 2.0 mg. Smaller doses than 0.15 mg, even in small infants, may result paradoxically in bradycardia because of a central stimulatory effect on the medullary vagal nuclei by a dose that is too low to provide anticholinergic effects on the heart. Atropine may be given by any route, including IV, endotracheal, interosseous, IM, and subcutaneous. Its onset of action occurs within 30 seconds, and its peak effect occurs between 1 and 2 minutes after an IV dose. The recommended adult dose is 0.5 mg every 5 minutes until the desired heart rate is obtained up to a maximum of 2 mg. For asystole, 1 mg is given intravenously and repeated every 5 minutes if asystole persists. Full vagal blockade usually is obtained with a dose of 2 mg in adults.

Because of its parasympatholytic effects, atropine should not be used in patients in whom tachycardia is undesirable. In patients after myocardial infarction or ischemia with persistent bradycardia, atropine should be used in the lowest dose possible to increase heart rate. Using the lowest possible dose will limit tachycardia, a potent contributor to increased myocardial oxygen consumption, which could lead to VF. In addition, atropine should not be used in patients with pulmonary or systemic outflow tract obstruction or idiopathic hypertrophic subaortic stenosis because tachycardia decreases ventricular filling and lowers cardiac output in this setting.

Sodium Bicarbonate

The administration of sodium bicarbonate results in an acid-base reaction in which bicarbonate combines with hydrogen to form carbonic acid, which dissociates into water and carbon dioxide. Because of the generation of carbon dioxide, adequate alveolar ventilation must be present to achieve the normal buffering action of bicarbonate. Use of sodium bicarbonate during CPR remains controversial because of its potential adverse effects and the lack of evidence showing any benefit from its use during CPR.[196,197]

Sodium bicarbonate is indicated for correction of significant metabolic acidosis, especially when signs of cardiovascular compromise are present. Acidosis itself may have a number of negative effects on the circulation, including depression of myocardial function by prolonging diastolic depolarization, depressing spontaneous cardiac activity, decreasing the electrical threshold for VF, decreasing the inotropic state of the myocardium, and reducing the cardiac response to catecholamines. Acidosis also decreases systemic vascular resistance and attenuates the

vasoconstrictive response of peripheral vessels to catecholamines. This effect is contrary to the desired effect during CPR. In addition, particularly in patients with a reactive pulmonary vascular bed, pulmonary vascular resistance is inversely related to pH. Rudolph and Yuan observed a twofold increase in pulmonary vascular resistance in calves when pH was lowered from 7.4 to 7.2 under normoxic conditions.[198] Therefore correction of even mild acidosis may be helpful in resuscitating patients who have the potential for increased right-to-left shunting through a cardiac septal defect, patent ductus arteriosus, or aortic-to-pulmonary shunt during periods of elevated pulmonary vascular resistance.

Multiple adverse effects of bicarbonate administration include metabolic alkalosis, hypercapnia, hypernatremia, and hyperosmolality. All of these adverse effects are associated with a high mortality rate. Alkalosis causes a leftward shift of the oxyhemoglobin dissociation curve, thus impairing release of oxygen from hemoglobin to tissues at a time when oxygen delivery already may be low. Alkalosis can result in hypokalemia, by enhancing potassium influx into cells, and ionic hypocalcemia, by increasing protein binding of ionized calcium. Hypernatremia and hyperosmolality may decrease tissue perfusion by increasing interstitial edema in microvascular beds. The marked hypercapnic acidosis that occurs during CPR on the venous side of the circulation, including the coronary sinus, may be worsened by administration of bicarbonate.[199,200] Myocardial acidosis during cardiac arrest is associated with decreased myocardial contractility. The mean venoarterial $P\text{CO}_2$ difference was 24 ± 15 mm Hg in five patients during CPR and actually increased from 16 to 69 mm Hg in one patient after administration of bicarbonate.[201] Another group showed a mean difference of 42 mm Hg between partial pressure of carbon dioxide in mixed venous blood ($P\text{v}\text{CO}_2$) and $P\text{a}\text{CO}_2$ during CPR. Paradoxical intracellular acidosis after bicarbonate administration is possible because of rapid entry of carbon dioxide into cells with a slow egress of hydrogen ion out of cells. Paradoxical intracellular acidosis in the central nervous system after bicarbonate administration has been proposed but not definitively shown. In neonatal rabbits recovering from hypoxic acidosis, bicarbonate administration increased both arterial pH and intracellular brain pH as measured by nuclear magnetic resonance spectroscopy.[202] In another study, intracellular brain ATP concentration in rats did not change during severe intracellular acidosis in the brain produced by extreme hypercapnia.[203] The rats who maintained ATP concentration even in the face of severe brain acidosis had no functional or histologic differences from normal control subjects. Using nuclear magnetic resonance spectroscopy of the brain in dogs during cardiac arrest and CPR, intracellular brain pH decreased to 6.29 with total depletion of brain ATP after 6 minutes of cardiac arrest. However, following effective CPR, ATP levels rose to 86% of pre-arrest levels and to normal by 35 minutes of CPR despite ongoing peripheral arterial acidosis (Fig. 41.18).[110] However, cerebral pH decreased in parallel with blood pH when CPR was started immediately after arrest. Bicarbonate administration ameliorated and did not worsen the cerebral acidosis, indicating that the blood-brain pH gradient is maintained during CPR.[204]

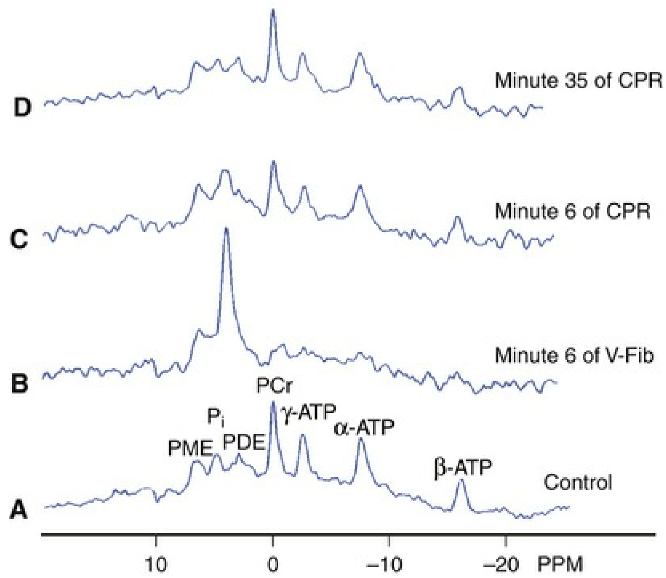

FIG. 41.18 ^{31}P magnetic resonance spectroscopy spectra from in situ dog brain during vest cardiopulmonary resuscitation *(CPR)* after a 6-minute delay in the onset of CPR from time of arrest. Each spectrum was acquired in 1 minute. The frequency of the inorganic phosphate *(P_i)* peak is pH dependent. Note complete absence of adenosine triphosphate *(ATP)* and phosphocreatine *(PCr)* and pH_i = 6.28 in *trace B* after 6 minutes of ventricular fibrillation *(v-fib)* without CPR. After 6 minutes of CPR *(trace C)*, ATP is more than 85% recovered, but pH is only 6.61. After 35 minutes of CPR *(trace D)*, pH_i has returned to 7. *PDE*, phosphodiesters; *PME*, phosphomonoesters; *PPM*, parts per million. (From Eleff SM, Schleien CL, Koehler RC, et al. Brain bioenergetics during cardiopulmonary resuscitation in dogs. Anesthesiology. 1992;76:77.)

The 2015 AHA guidelines state that sodium bicarbonate has not been shown to improve outcome during CPR and only recommends its use in special situations, such as intoxications.[118] A Cochrane study looking at the use of empirical sodium bicarbonate administration versus placebo in out-of-hospital cardiac arrests in 874 adults found no difference in survival to the hospital.[205] Levy reviewed more than 30 animal studies evaluating the efficacy of sodium bicarbonate administration during CPR.[206] Among studies with survival as the primary outcome, four showed benefit and seven did not. When assessing myocardial performance, 12 studies concluded that sodium bicarbonate worsened performance, 2 studies showed no difference, and no study showed benefit. When reviewing 19 retrospective human adult studies examining mortality rates, 8 of these suggested a deleterious effect of sodium bicarbonate, 11 showed no difference in outcomes, and none showed benefit.[206]

In a large retrospective study of pediatric patients with in-hospital cardiac arrest, it was found that survivors were less likely to receive sodium bicarbonate than nonsurvivors. However, nonsurvivors were also observed to have a longer CPR duration, as well as more doses of calcium, vasopressin, and epinephrine.[9] A subsequent retrospective study by Raymond et al.[207] examined sodium bicarbonate use after the institution of the 2010 AHA guidelines. While they found that sodium bicarbonate use for in-hospital cardiac arrest had been decreasing, its use was still associated with decreased survival at 24 hours and hospital discharge when given outside current pediatric advanced life support recommendations.[207]

When $PaCO_2$ and pH are known, the dose of bicarbonate to correct the pH to 7.4 is calculated using the following equation:

$$\text{Sodium bicarbonate (mEq)} = 0.3 \times \text{weight (kg)} \times \text{Base deficit} \qquad \textbf{Eq. 41.1}$$

(Because of its possible adverse effects and the large venous to arterial carbon dioxide gradient that develops during CPR, we recommend giving half the dose that would be given based on a volume of distribution of 0.6.) If blood gases are not available, the initial dose is 1 mEq/kg, followed by 0.5 mEq/kg every 10 minutes of ongoing arrest. Alveolar ventilation must be maintained because of the generation of carbon dioxide and can be assessed only by serial measurements of arterial blood gases and pH. Because of the potential adverse effects of bicarbonate, the indications for its use at this time are limited to cardiac arrest associated with hyperkalemia, patients with preexisting metabolic acidosis, and after approximately 10 minutes of CPR.

$EtCO_2$ monitoring is useful during CPR because it provides important information regarding both pulmonary and cardiac function. $EtCO_2$ is measured instantaneously in the exhaled gas of every breath. In the absence of lung disease, $EtCO_2$ correlates closely with $PaCO_2$ provided pulmonary blood flow is at least 20% to 25% of normal. As a respiratory monitor, $EtCO_2$ analyzers accurately distinguish a tracheal ($EtCO_2$ >10) from an esophageal ($EtCO_2$ <5) intubation in infants and children.[208-213] Because measurements are made with every breath, dislodgment of the endotracheal tube from the trachea can be identified immediately. When cardiac output is extremely low, as occurs during ineffective CPR, delivery of carbon dioxide to the lungs is so limited that the total amount exchanged across the alveolar-capillary membrane is markedly reduced. In this situation, the measured $EtCO_2$ is very low even when $PaCO_2$ is elevated. As cardiac output increases, $EtCO_2$ increases and the difference between end-tidal and arterial CO_2 becomes smaller.[214] $EtCO_2$ has been correlated with CPP, the critical parameter for resuscitation of the heart.[214] However, a low $EtCO_2$ may occur in the presence of adequate cardiac output during CPR after the administration of epinephrine because of its ability to increase intrapulmonary shunting.[185,193,215] In this case, a low $EtCO_2$ underestimates cardiac output. Other causes of low $EtCO_2$ include airway obstruction, tension pneumothorax, pericardial tamponade, pulmonary embolism, hypothermia, severe hypocapnia (which occurs commonly with overaggressive hand ventilation), and esophageal intubation.

Levine et al.[211] monitored $EtCO_2$ in 150 adults with an out-of-hospital cardiac arrest who had electrical activity but no pulse.[216] They found that after 20 minutes of ACLS, an $EtCO_2$ level of 10 mm Hg or less successfully predicted survival to hospital admission with a sensitivity, specificity, and positive- and negative-predictive value of 100%. Grmec and Klemen prospectively studied the initial, average, maximal, minimal, and final $EtCO_2$ as a prognostic indicator for outcomes in adult resuscitation.[217] They found that using an initial, average, and final $EtCO_2$ level of 10 mm Hg identified 100% of patients who were successfully resuscitated, with specificity of 74%, 90%, and 81%, respectively.[217]

The 2015 AHA guidelines state that while use of $EtCO_2$ as an indicator of cardiac output may be useful in adults (evidence class IIb), currently no studies have evaluated the use of $EtCO_2$ in pediatric arrests.[118] There have been no human trials studying whether titrating resuscitation efforts to a specific number can affect clinical outcomes. In a piglet model of CPR, it was found that CPR guided by a target $EtCO_2$ was as effective as CPR guided by depth monitor, video monitor, and verbal feedback. Whereas no specific value has yet to be established, given the noninvasive nature of $EtCO_2$ monitoring and also extrapolating from adult data,[218] maintaining an $EtCO_2$ of greater than 10 to 15 mm Hg through the use of $EtCO_2$ monitoring is recommended during pediatric arrests.[153]

Other Alkalinizing Agents

A number of other alkalinizing agents have been used experimentally in animals and humans. However, none has demonstrated any real advantages over sodium bicarbonate. Carbicarb, a solution of equimolar amounts of sodium bicarbonate and sodium carbonate, corrects metabolic acidosis without many of the adverse effects of sodium bicarbonate.[74] The buffering action of sodium carbonate occurs by consumption of carbon dioxide with generation of bicarbonate ion, as illustrated in the following equation:

$$Na_2CO_3 + CO_2 + H_2O = 2\,HCO_3^- + 2Na^+ \qquad \textbf{Eq. 41.2}$$

During CPR, Carbicarb administration resulted in a greater increase in arterial pH and smaller increases in $PaCO_2$, lactate, and serum osmolality in animals.[74,219,220] However, Carbicarb was not superior to sodium bicarbonate when used for hypovolemic shock in rats.[221]

Dichloroacetate (DCA) increases the activity of pyruvate dehydrogenase, which facilitates the conversion of lactate to pyruvate.[222] When administered to patients with lactic acidosis, DCA decreased lactate concentration by half and increased bicarbonate concentration and pH.[223] In other studies, DCA improved cardiac output, possibly by increasing myocardial metabolism of lactate and carbohydrate.[224,225] In a multicenter trial of patients with lactic acidosis, DCA did not improve outcome when compared with sodium bicarbonate.[226]

Tromethamine (THAM; tris-hydroxymethyl-aminomethane) is an organic amine that combines with a hydrogen ion, causing CO_2 and H_2O to combine to form bicarbonate and a hydrogen ion. A dose of 3 mL/kg should raise the bicarbonate concentration by 3 mEq/L. Adverse effects of THAM include hyperkalemia, hypoglycemia, and acute hypocarbia resulting in apnea. In addition, peripheral vasodilation may occur after administration of THAM during CPR, which is an undesirable effect. THAM is contraindicated in patients with renal failure.

Calcium

Recommendations for use of calcium in CPR are restricted to a few specific situations, namely, hypocalcemia, hyperkalemia, hypermagnesemia, and calcium

channel blocker overdose. These restrictions are based on the possibility that exogenously administered calcium may worsen ischemia/reperfusion injury. Intracellular calcium overload occurs during cerebral ischemia by the influx of calcium through voltage- and agonist-dependent (eg, *N*-methyl-D-aspartate) calcium channels. Calcium plays an important role in the process of cell death in many organs, possibly by activating intracellular enzymes such as nitric oxide synthase, phospholipase A and C, and others.[227,228] Calcium channel blockers improve blood flow and function after ischemia to the heart, kidney, and brain.[229-231] Calcium channel blockers also raise the threshold of the ischemic heart to VF.[232] For these reasons, it appears that the recommended restrictions for use of calcium during CPR are well founded. On the other hand, no studies have shown that elevation of plasma calcium concentration, which occurs after calcium administration, worsens outcome of cardiac arrest. Because the normal ratio of extracellular to intracellular calcium is on the order of 1000 : 1 to 10,000 : 1, it seems unlikely that the rate of influx of calcium into cells would be influenced by a relatively small increase in its extracellular concentration.

The calcium ion is essential in myocardial excitation-contraction coupling, in increasing ventricular contractility, and in enhancing ventricular automaticity during asystole. Ionized hypocalcemia is associated with decreased ventricular performance and peripheral blunting of the hemodynamic response to catecholamines.[233,234] In addition, severe ionized hypocalcemia has been documented in adults experiencing out-of-hospital cardiac arrest (mean Ca 0.67 mmol/L), during sepsis, and in animals during prolonged CPR.[234-236] Thus patients at risk for ionized hypocalcemia should be identified and treated as expeditiously as possible. Both total and ionized hypocalcemia may occur in patients with chronic or acute disease. Total body calcium depletion leading to total serum hypocalcemia occurs in patients with hypoparathyroidism, DiGeorge syndrome, renal failure, pancreatitis, and long-term use of loop diuretics. Ionized hypocalcemia occurs after massive or rapid transfusion of blood products, a result of citrate and other preservatives in stored blood products that bind calcium. The magnitude of hypocalcemia in this setting depends on the rate of blood administration, the total dose, and the hepatic and renal function of the patient. Administration of 2 mL/kg/min of citrated whole blood causes a significant decrease in ionized calcium concentration in anesthetized patients.

The pediatric dose of calcium chloride for resuscitation is 20 mg/kg. The adult dose is 200 mg (2 mL of the 10% solution). Calcium gluconate is as effective as calcium chloride in raising ionized calcium concentration during CPR. Calcium gluconate is given at a dose of 30 to 100 mg/kg, with a maximum dose of 2 g in pediatric patients. Calcium should be given slowly through a large-bore, free-flowing IV line, preferably a central venous line. Severe tissue necrosis occurs when calcium infiltrates into subcutaneous tissue. When administered too rapidly, calcium may cause bradycardia, heart block, or ventricular standstill.

Srinivasan et al. reviewed 1477 consecutive pediatric cardiopulmonary events submitted to the National Registry of Cardiopulmonary Resuscitation and reported on the prevalence of calcium administration.[237] Of the children in the registry, 659 were documented as receiving calcium. Calcium was more likely to be used in pediatric facilities, ICUs, and the settings of cardiac surgery, CPR performed for more than 15 minutes, asystole, and concurrently with other advanced life support

medications. After controlling for confounding factors (demographics, immediate precipitating causes, arrest rhythm, concurrent ACLS medications, and duration of CPR), calcium administration during CPR was independently associated with poor survival to discharge and unfavorable neurologic outcomes. They found that 21% of patients survived to hospital discharge when calcium was used, compared with 44% who survived when calcium was not used. Only 15% of patients had a favorable neurologic outcome when calcium was used, compared with 35% with a favorable outcome when calcium was not administered.[237]

Glucose

Administration of glucose during CPR should be restricted to patients with documented hypoglycemia because of the possible detrimental effects of hyperglycemia on the brain during or following ischemia. Myers found that infant monkeys that received glucose before cardiac arrest were more likely to develop seizures, prolonged coma, and brain death with cerebral necrosis than were those that received saline solution.[238] Siemkowicz and Hansen confirmed this finding when they demonstrated that after 10 minutes of global brain ischemia, the neurologic recovery of hyperglycemic rats was worse than that of normoglycemic control subjects.[239] The mechanism by which hyperglycemia exacerbates ischemic neurologic injury may be increased production of lactic acid in the brain by anaerobic metabolism. During ischemia under normoglycemic conditions, brain lactate concentration reaches a plateau. In a hyperglycemic milieu, however, brain lactate concentration continues to rise for the duration of the ischemic period. The severity of intracellular acidosis during ischemia is directly proportional to the preischemic glucose concentration.[240] The negative effect of hyperglycemia during brain ischemia is predicated on the presence of at least a small amount of blood flow to brain tissue. In one study, collaterally perfused but not end-arterial brain tissue had greater neuronal damage during hyperglycemic focal ischemia (Fig. 41.19).[241]

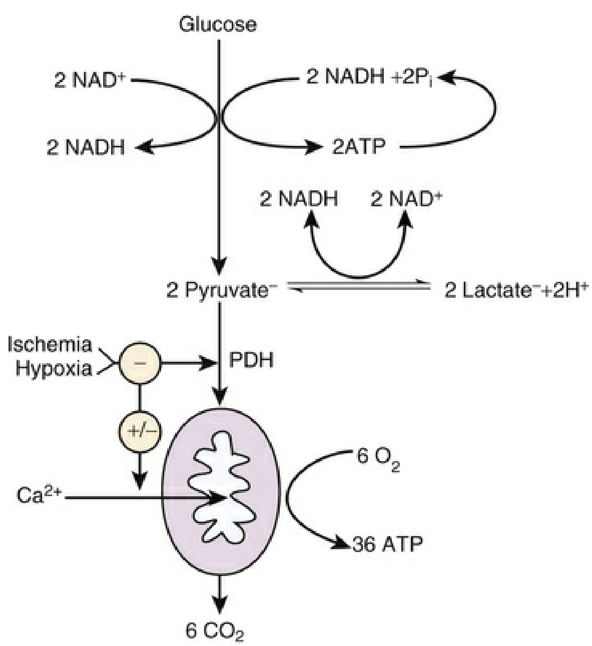

FIG. 41.19 Schematic diagram illustrating the aerobic/anaerobic metabolism of glucose. Oxidation of pyruvate to CO_2 (and H_2O) by pyruvate dehydrogenase and citric acid cycle enzymes is retarded to blocked by oxygen deficiency, causing a reduction of pyruvate to lactate. If the adenosine triphosphate *(ATP)* formed during glycolysis is hydrolyzed (ie, if the ATP concentration stays constant), one molecule of H^+ is released for each molecule of lactate formed. If the mitochondria retain a membrane potential, they will sequester excess calcium entering the cell; however, if they deenergized (with collapse of their membrane potential), they will release their calcium content. *ADP*, adenosine diphosphate; *NAD*, nicotinamide adenine dinucleotide; *NADH*, reduced nicotinamide adenine dinucleotide; P_i, intracellular phosphorus; *PDH*, pyruvate dehydrogenase.

Clinical studies show a direct correlation between the initial post–cardiac arrest serum glucose concentration and poor neurologic outcome.[230,242] However, a higher glucose concentration may just be an endogenous response to severe stress and thus a marker and not the cause of more severe brain injury.[75] In piglets, postischemic administration of glucose did not worsen neurologic outcome after global hypoxia-ischemia.[243] However, given the likelihood of additional ischemic and hypoxic events in the postresuscitation period, it seems prudent to maintain serum glucose in the normal range. Administration of insulin to hyperglycemic rats after global brain ischemia improved neurologic outcome.[244] The effect of insulin may be independent of its ability to lower blood glucose because these investigators later showed that normoglycemic insulin-treated rats had a better outcome than normoglycemic placebo-treated control subjects.[245]

Using intensive insulin therapy, Van den Bergh et al. strictly controlled the blood glucose levels of adults in a surgical ICU, maintaining levels between 80 and 110 mg/dL.[246,247] This control of blood glucose levels appeared to reduce mortality and protect the central and peripheral nervous systems. However, a subsequent study in a medical ICU showed no difference in mortality between the intensive insulin therapy and control groups.[248] Another study showed that the use of intensive insulin therapy to maintain normoglycemia was associated with increased episodes of hypoglycemia.[249] Currently few pediatric data are available on the efficacy and safety of strict glucose control. Further study needs to be done to determine the blood glucose level at which to trigger intensive insulin therapy, as well as the optimal ranges at which to maintain blood glucose concentration.

Some groups of patients, including premature infants and debilitated patients with low endogenous glycogen stores, are more prone to the development of hypoglycemia during and after a physiologic stress (eg, surgery).[250] Hypoglycemia poses a higher risk in the immature pediatric brain compared with the adult brain. Bedside monitoring of serum glucose is critical during and after a cardiac arrest and allows for intervention before the critical point of low substrate delivery is reached. The dose of glucose needed to correct hypoglycemia is 0.5 to 1.0 g/kg given as 10% dextrose in infants. The osmolarity of 50% dextrose is approximately 2700 Osm/L and is associated with intraventricular hemorrhage in neonates and infants.

Management of Ventricular Fibrillation

The management of lethal ventricular arrhythmias traditionally has not played a major role in resuscitation teaching or management for children because of the low incidence of these arrhythmias. Newer evidence gathered in the environment of rapid access defibrillation suggests that up to 19% of the presenting rhythms in pediatric arrests is ventricular in origin, and this represents up to 5% to 15% of all pediatric victims of out-of-hospital cardiac arrest.[17,251] The incidence increases with age. Approximately 25% of children experiencing in-hospital cardiac arrest have ventricular tachycardia (VT) or fibrillation.[126] Moreover, the growing and aging population of children palliated for complex congenital heart disease in which the occurrence of ventricular arrhythmias may be much higher than in the general pediatric population requires greater attention to ventricular arrhythmias than in the past. Other potential causes of ventricular arrhythmias include familial and acquired prolonged QT syndrome, other arrhythmogenic ventricular conditions, cardiomyopathies, myocarditis, drug intoxications (such as illicit and accidental ingestion and therapeutic misadventures), electrolyte derangements (eg, magnesium, calcium, potassium, or glucose), and hypothermia.[252,253]

Advances have been made in the management of ventricular arrhythmias. Rapid access to defibrillation has been shown to reduce mortality in adults, and the development of public access defibrillation and AEDs has flowed from this knowledge. Initially AED devices had little utility for children, but the development of current-reducing electrodes and specific pediatric algorithms has made public access defibrillation a reality for children, and AEDs have been deployed in the many environments in which children would be the primary beneficiaries (eg, schools and public swimming pools). When automated external defibrillators are used within 3 minutes of adult-witnessed ventricular fibrillation in children, long-term survival can occur in more than 70% of cases.[254-256] The technique of current delivery has undergone change with the development and deployment of biphasic defibrillators, which may offer increased efficacy with reduced risk of myocardial injury. Finally, amiodarone has started to replace lidocaine as the drug of choice for refractory ventricular arrhythmias and atrial arrhythmias. The role of each of these factors in the resuscitation of pediatric arrest victims is discussed in the following section.

Defibrillation

VF is the chaotic electrical excitation of the ventricle, and the definitive treatment in accordance with the 2015 AHA guidelines is defibrillation.[47,189,257] The electrical mechanism is usually explained as a reentrant depolarization of the myocardium, initially in waves, which then take more circuitous routes and degenerate into smaller reentry circuits resulting in loss of the rhythmic contractile function of the ventricles.[258] This changing pattern of reentry circuits corresponds with the change from coarse to fine VF as the duration of fibrillation persists and may correlate with deterioration in energy stores associated with persistence of fibrillation.[5,259,260] Similarly, most cases of VT are attributable to reentrant mechanisms, although increased automaticity is the likely mechanism in persons with drug-induced torsades de pointes and electrolyte disturbances such as hypokalemia and hypomagnesemia.[261] Nonpulsatile VT with loss of effective contractile function of the heart rapidly deteriorates into VF. Loss of effective ventricular function with these

arrhythmias requires emergent management.

The standard for management of VF and pulseless VT is immediate defibrillation and high-quality CPR. Although the lowest energy dose for effective defibrillation and the upper limit for safe defibrillation in infants and children are not known, energy doses greater than 4 J/kg (up to 9 J/kg) have effectively defibrillated children.[153] The standard voltage dose for pediatric defibrillation is 2 J/kg. If unsuccessful, successive doses of defibrillation are repeated at 4 J/kg or more, not to exceed 10 J/kg or the maximum adult dose.[115] This dosage is based on data reported by Gutgesell et al. in 1976.[262] They reported 71 defibrillation attempts in 27 children. Efficacy was 91% with 2 J/kg and 100% with 4 J/kg. After initial defibrillation, CPR is performed for 2 minutes, followed by a rhythm check and then repeat shock if required. This sequence may then be repeated, with consideration given to initiate vasopressor therapy. Rhythms that fail to respond to three rounds are defined as "shock resistant." In this setting, the standard as defined in the AHA guidelines is amiodarone, 5 mg/kg or lidocaine (or magnesium for torsades de pointes), followed by 2 minutes of CPR and continuation of the rhythm check-shock-CPR/vasopressor cycle (Fig. 41.21). Reversible causes of VT/VF should also be investigated. Success in resuscitation is incumbent on immediate defibrillation with immediate CPR in between delivery of shocks.

It is important to continue to deliver appropriate CPR while gathering defibrillation equipment.[263,264] Additional important considerations when delivering shocks include paddle size, position, contact pressure, and use of electrode paste. Large paddles reduce thoracic impedance, and infants older than 1 year or weighing more than 10 kg should be treated with adult paddles.[265] Adhesive patch electrodes are an acceptable alternative to paddles and can be used when available if their use does not cause a delay in therapy.[266-268] Paddles should be positioned to achieve current flow through the heart, and an anterior-apex or anterior-posterior placement is selected. Contact pressure has been demonstrated to reduce impedance. Firm pressure, which commonly is not properly applied, is required.[269] Proper electrode paste or gel is necessary. Care is required to avoid smearing paste across the chest wall because doing so can lead to arcing of the circuit and a resultant short circuit. Bare paddles, ultrasound gel, pads soaked in saline solution, and alcohol pads are not acceptable alternatives to electrode cream or paste.[189]

The role of immediate defibrillation has come under question. The efficacy of defibrillation declines rapidly as fibrillation persists. When an arrest is witnessed and a defibrillator is immediately available, defibrillation likely will be successful. With any delay in resuscitation, the success of initial defibrillation declines at a rate estimated at between 7% and 10% per minute of continued fibrillation.[154] A number of studies have demonstrated in both animals and adults that if more than 3 to 5 minutes of fibrillation have occurred before institution of defibrillation, use of CPR for 90 to 180 seconds to restore myocardial energy stores will improve the likelihood of conversion to a perfusing rhythm with defibrillation.[6,8,270,271] Given the frequency of unwitnessed arrest in children and the relatively low frequency of ventricular arrhythmias, CPR first may be the appropriate response in children.

Use of biphasic defibrillators is another important advance in the management of tachyarrhythmias. Studies suggest that defibrillation with a biphasic waveform can be achieved with lower energy and less myocardial injury than with a standard monophasic defibrillator current.[272,273] The first commercially available devices were

approved by the US Food and Drug Administration in 1996. An evidence-based review was undertaken by the AHA and published in 1998.[45] The reviewers concluded that "low-energy, non-progressive biphasic waveform defibrillators may be used for both out-of-hospital and in-hospital VF arrest, including persistent or recurrent VF that does not respond to the initial low-energy shock." These conclusions were based on observational studies and case reports. Subsequently, Schneider et al. reported a randomized controlled trial of biphasic versus monophasic defibrillation for out-of-hospital cardiac arrest.[274] Of 338 arrests, 115 patients had VF and were shocked with an AED. Defibrillation in the initial shock series was successful in 98% of patients receiving biphasic shocks but in only 69% of those receiving monophasic shocks ($p < .0001$), providing further evidence that biphasic waveforms are more efficacious than monophasic waveforms (Fig. 41.20).

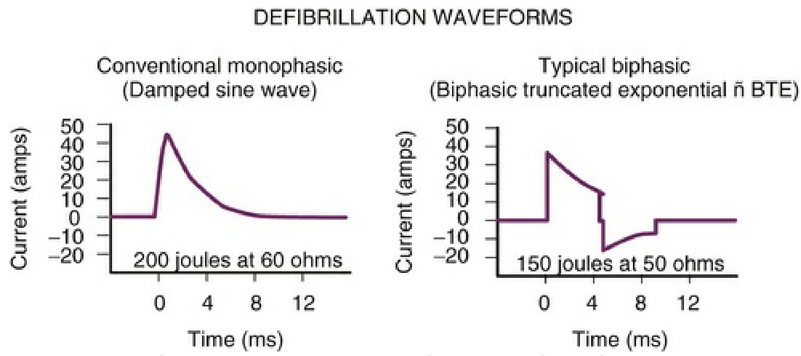

FIG. 41.20 Schematic patterns of current flow for conventional monophasic and typical biphasic defibrillator waveforms.

Biphasic shocks appear to be at least as effective as monophasic shocks and less harmful. Published data on children are limited to case reports.[275] Animal data are supportive of the use of biphasic defibrillators in infants and children. Clark et al. demonstrated in a piglet model that low-energy biphasic shocks were superior to monophasic shocks for converting catheter-induced VF.[276] Both Tang et al. and Berg et al. studied the use of AEDs equipped with energy-reducing electrodes and found increased efficacy compared with monophasic waveforms.[5,277] Berg et al. also demonstrated improved LV function 5 hours after resuscitation.

According to the 2015 AHA recommendations, with a manual defibrillator, dosage recommendations for children remain 2 J/kg for the first attempt followed by 4 J/kg for subsequent attempts.[5,49,278] This dose was increased from the 2005 guidelines, which cited studies that demonstrated the ineffectiveness of 2 J/kg at achieving ROSC. Subsequent to the publication of the 2010 AHA recommendations, a review of the National Registry of Cardiopulmonary Resuscitation data compared the effect of 2 J/kg with historical controls and a 4 J/kg initial shock dose in VF and pulseless VT. The authors found that termination of the arrhythmia with an initial shock dose of 2 J/kg was significantly less effective than historical controls (56% vs. 91%). A higher initial dose of 4 J/kg was associated with less successful ROSC than the 2 J/kg dose. On the basis of these conflicting data, they concluded that the optimal initial shock dose has yet to be determined.

In the early 1990s, as part of an AHA campaign to improve the abysmal rates of resuscitation from out-of-hospital cardiac arrest in adults, the development and

deployment of AEDs were initiated. Both fixed and escalating dose devices were developed; however, the initial dose usually was at least 150 J in adults. Because of the high fixed-energy doses, the devices were not recommended for use in children younger than 9 years. Moreover, use of these devices for young children was questioned because the arrhythmia detection algorithms used in these devices were developed for adults. Cecchin et al. used the Agilent Heartstream FR2 Patient Analysis System to analyze 696 five-second rhythms from 191 children younger than 12 years.[279] Analysis revealed 100% accuracy for nonshockable rhythms and 96% accuracy for VF. This is similar to the accuracy reported for adults. In a more recent study, Atkinson et al. tested the accuracy of the Lifepak 500 AED on 1561 fifteen-second rhythms from 203 children aged 1 day to 7 years.[261] The device correctly identified 99% of coarse VF as shockable and 99.1% of nonshockable rhythms. A number of manufacturers (Zoll and Agilent) have developed energy-reducing electrodes that should allow use of these devices in young children.[261]

Since the 2000 AHA guidelines, data have shown that AEDs can be safely and effectively used in children of all ages. Current guidelines recommend use of an AED in children between the ages of 1 and 8 years who have no signs of circulation. The device should be adapted to deliver a pediatric dose with the use of a pediatric attenuator system that decreases the delivered energy to a dose suitable for children. When an attenuator system is not available, then the standard adult pads with corresponding dose should be delivered. In children younger than 1 year of age, a manual defibrillator is preferred; however, an AED with or without a pediatric attenuator may be used if necessary.[256]

Antiarrhythmics

Amiodarone is an effective antiarrhythmic agent for both atrial and ventricular arrhythmias. The role of amiodarone in cardiac arrest was established after a series of studies demonstrated efficacy and superiority of amiodarone over lidocaine in the management of refractory VF and pulseless VT in adults. Compared with lidocaine, amiodarone led to substantially higher rates of survival to hospital admission in patients with shock-resistant out-of-hospital VF.[280] These findings led to major changes in the AHA guidelines for management of ventricular arrhythmias (Table 41.1 and Figs. 41.21 and 41.22).

TABLE 41.1

Drug Therapy for Pulseless Arrest

Drug	Route of Administration	Dosage	How Applied
Epinephrine	IV, intraosseous, endotracheal	10 µg/kg; max dose 1 mg IV/IO	1 : 10,000 (0.1 mL/kg)
		100 µg/kg; max dose 2.5 mg ET	1 : 1000 should be used for ETT (0.1 mL/kg)
Atropine	IV, intraosseous, endotracheal, subcutaneous	0.02 IV/IO mg/kg; min dose 0.1 mg, max dose 0.5 mg, repeat once as needed, ET dose 0.04-0.06 mg/kg	
Sodium bicarbonate	IV, intraosseous	1 mEq/kg/dose	1 mEq/mL
		or	0.5 mEq/mL
		0.3 × weight (kg) × base deficit	
Calcium chloride	IV (intraosseous)	20 mg/kg	10% solution (100 mg/mL); administer slowly
		0.2 mL/kg	
Lidocaine	IV (intraosseous),	1 mg/kg	1%, 2%, 4% solution

	endotracheal		
Amiodarone	IV (intraosseous)	5 mg/kg	If stable, load over 20-60 minutes IV push during cardiac arrest
Magnesium	IV (intraosseous)	25-50 mg/kg for torsades des pointes or max dose 2 g	50% solution

ETT, endotracheal tube; *IV,* intravenous.

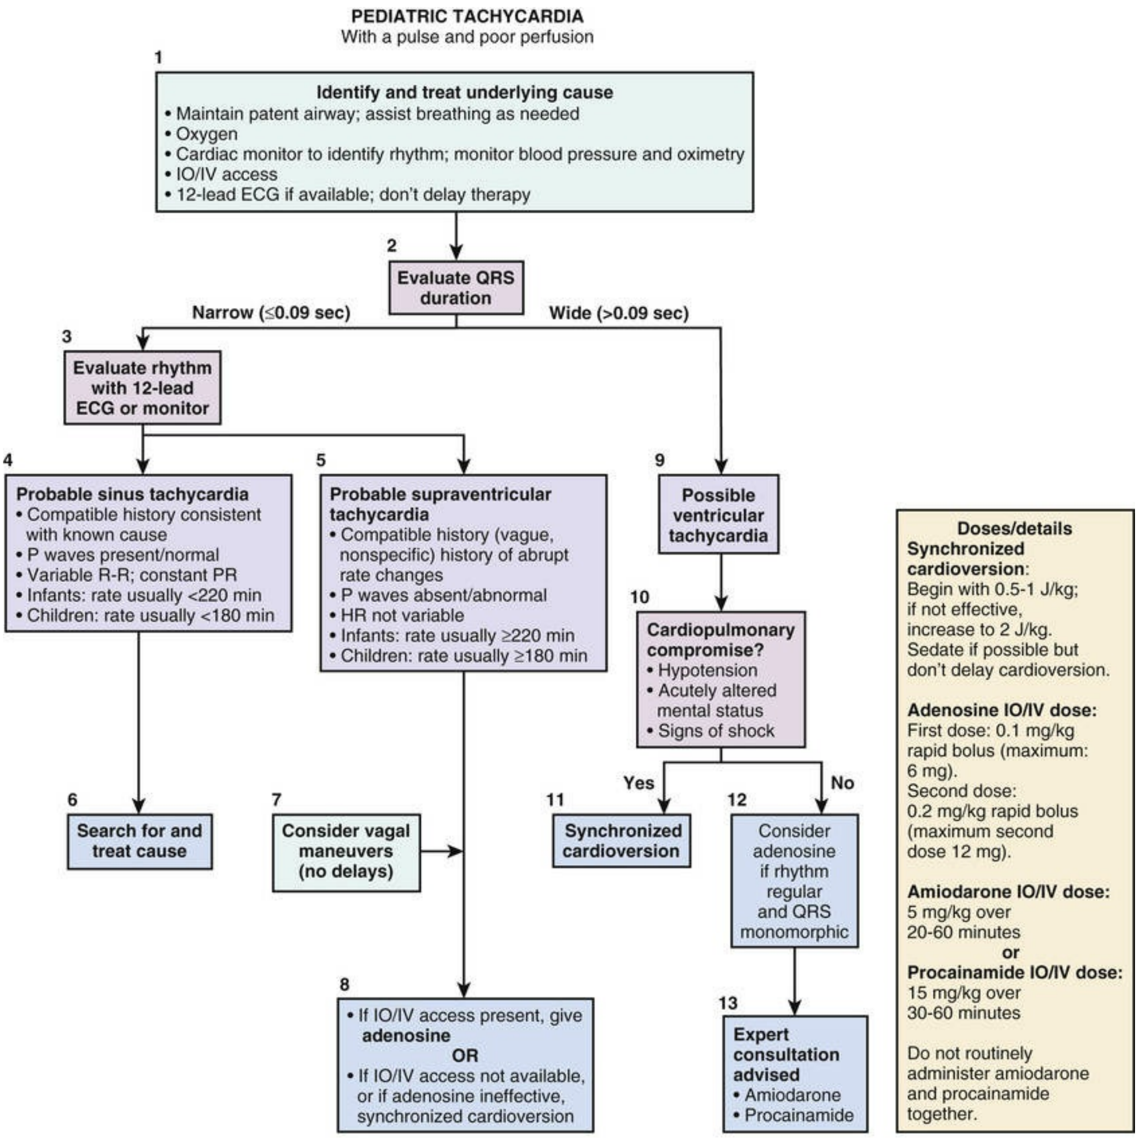

FIG. 41.21 American Heart Association guidelines for management of ventricular arrhythmias. *ABCs,* airway, breathing, and circulation; *BLS,* basic life support; *CPR,* cardiopulmonary resuscitation; *ECG,* electrocardiogram; *IO,* intraosseous; *IV,* intravenous; *PEA,* pulseless electrical activity; *TT,* tracheal tube; *VF,* ventricular fibrillation; *VT,* ventricular tachycardia.

Early reports on use of oral amiodarone in children were favorable.[280-284] Data on amiodarone use in children are limited to case reports and descriptive case series.[285-289] Nevertheless, it is now used widely for serious pediatric arrhythmias. It appears to be effective and have an acceptable short-term safety profile. In 2008, we examined the practice patterns of amiodarone use during in-hospital cardiac arrest. In this retrospective cohort study, it was noted that there has been a significant increase in amiodarone use for VF/VT events during the past 5 years. It was also noted that the frequency of amiodarone use in adults correlated positively with the number of intensive care beds, suggesting that the emerging data and national guidelines affect resuscitation practice patterns.[84]

The growing pediatric experience among experts and inference from adult studies led to inclusion of amiodarone in the 2000 AHA pediatric advanced life support guidelines and continued in the 2015 AHA pediatric advanced life support guidelines as a drug of choice, alongside lidocaine, for pulseless VT.[49] For hemodynamically stable VT, it is also a drug of choice, with the level of evidence classified as IIb. Procainamide remains an alternative drug choice. Amiodarone is

commonly used for management of postoperative atrial and junctional ectopic tachycardia, especially in patients with ventricular pacing wires in place.

The wide range of effectiveness of amiodarone is demonstrated by the array of indications noted in the 2015 AHA guidelines for adults.[189] Its role in the management of atrial arrhythmias in adults includes the following: as an adjunct to electrical cardioversion of refractory paroxysmal supraventricular tachycardia and atrial tachycardia, for rate control when digoxin has been ineffective, for pharmacologic conversion of atrial flutter, and for control of rapid ventricular response in pre-excited atrial tachyarrhythmias. It is the drug of choice for junctional tachycardia with poor function. If function is preserved, amiodarone is an acceptable alternative to a β-blocker or calcium channel blocker. Its role in ventricular arrhythmias is outlined in Box 41.2.

Box 41.2

Amiodarone (IV)

- IV amiodarone affects sodium, calcium channels, and α- and β-adrenergic blocking properties. The drug is useful for treatment of both atrial and ventricular arrhythmias.

- Amiodarone is also helpful for ventricular rate control of rapid atrial arrhythmias in patients with severely impaired LV function when digitalis has proved ineffective. Amiodarone is recommended after defibrillation and epinephrine in cardiac arrest with persistent VT or VF.

- Amiodarone is effective for control of hemodynamically stable VT, polymorphic VT, and wide-complex tachycardia of uncertain origin.

- Amiodarone is an adjunct to electrical cardioversion of refractory PSVTs, atrial tachycardia, and pharmacologic cardioversion of AF.

- Amiodarone can control rapid ventricular rate due to accessory pathway conduction in preexcited atrial arrhythmias.

AF, atrial fibrillation; *LV,* left ventricular; *PSVT,* paroxysmal supraventricular tachycardia; *VF,* ventricular fibrillation; *VT,* ventricular tachycardia.

The pharmacology of amiodarone is complex and may partially explain the wide range of efficacy. It is poorly absorbed orally and must be loaded intravenously in urgent situations. It is primarily classified as a Vaughn-Williams class III agent that blocks the ATP-sensitive outward potassium channels, causing prolongation of the action potential and refractory period. However, this effect requires intracellular accumulation. Upon IV loading, the antiarrhythmic effects primarily result from noncompetitive α- and β-adrenergic receptor blockade, calcium channel blockade, and effects on inward sodium current, causing a decrease in anterograde conduction across the atrioventricular node and an increase in the effective atrioventricular refractory period. The full antiarrhythmic impact requires a loading period for up to 1 to 3 weeks to achieve intracellular levels and full potassium channel blocking

effects. Prolongation of the QT interval, an effect resulting from K-ATP channel blockade, is commonly described with amiodarone use; however, it does not manifest until several days into loading, underscoring its different effects during the acute period and after loading is accomplished. These effects are evident throughout all cardiac tissue, which may explain amiodarone's efficacy for so many arrhythmias, both atrial and ventricular. The α-adrenergic blockade leads to vasodilation, which may increase coronary blood flow.

Immediate hemodynamic effects of amiodarone are caused by the solubilizing agent Tween 80, which has both vasodilating and myocardial depressant effects.[290] Hypotension is commonly reported with IV administration and may limit the rate at which the drug can be given. The overall hemodynamic impact of intravenous administration depends on the balance of its effect on rate control, myocardial performance, and vasodilation. Cardiac output is usually unchanged or increases despite the decreased contractility because of both rate control and vasodilation. The effect on systemic vascular resistance and the limited impact on contractility make amiodarone the drug of choice for use in patients with impaired cardiac function.

The drug is highly lipid soluble, giving it a large volume of distribution, which accounts for the need for loading over many days. Until all tissues are saturated, rapid redistribution out of the vascular compartment may lead to early recurrence of arrhythmias. Once tissue saturation has occurred, the half-life is estimated to be between 13 and 103 days.

Dosage recommendations for children are based on limited clinical studies and extrapolation of adult data. For life-threatening arrhythmias, the usual recommended dose is 5 mg/kg administered intravenously. This dose can be repeated if necessary to control the arrhythmia. IV loading doses are followed by a continuous infusion of 10 to 20 mg/kg/day if there is a risk for arrhythmia recurrence. The ideal rate of bolus administration is unclear, but once diluted the drug is given by IV push in adults. The potential for profound vasodilation in children has led to concern by some pediatric intensivists and cardiologists, who recommend that amiodarone be given over 10 minutes as recommended in the package insert. This concern may not be valid in the pulseless arrest setting. Some delay always occurs with the current formulation of the IV drug because it must be diluted before it can be administered. Drug dilution should not delay administration of additional shocks. Averages of five shocks are delivered to adults with refractory VF before amiodarone is administered. An alternative dosing regimen for children is administration of 1 mg/kg pushes every 5 minutes up to 5 mg/kg. This dose can be repeated up to 10 mg/kg if the arrhythmia is not controlled. Use of the small-aliquot bolus technique may be particularly appropriate for infants younger than 6 to 12 months.

Amiodarone administered intravenously leaches plasticizers, particularly DEHP, from polyvinyl chloride. This effect is enhanced at low infusion rates and at higher drug concentrations and may be minimized by frequent intermittent boluses. Whether these plasticizers have any significant toxicity at these doses is unknown, although evidence indicates testicular vacuolization in rodents. Additional caution is warranted in neonates because the solution contains benzyl alcohol, which is associated with metabolic acidosis and death in premature infants (gasping syndrome). Identification of the potential for these adverse events has led the manufacturer to issue a statement to health care professionals stating that use of

intravenously administered amiodarone in pediatrics is not recommended. The AHA has responded with a reiteration of the recommendation for IV amiodarone use in the 2015 guidelines for emergency cardiac care. In the recommendation it concludes that practitioners should obtain expert consultation because complications may include bradycardia, heart block, and torsades de pointes VT. Adverse reactions to amiodarone can be life-threatening. The drug prolongs the QT interval. In a series by Etheridge et al., 29 of 50 infants and children experienced mild-to-moderate prolongation of the QTc.[286] In the series by Burri et al., "most" infants experienced QTc prolongation.[285] Although none of the pediatric case series described the development of drug-induced arrhythmias in patients, amiodarone-induced torsades de pointes has been described in case reports, and, although less common than in adults, caution is warranted.[291] Use of amiodarone should be avoided in combination with other drugs that prolong the QT interval. In addition, caution should be exercised in the setting of hypomagnesemia and other electrolyte abnormalities that predispose to torsades de pointes. Severe bradycardia and heart block have been described, especially in the postoperative period, and ventricular pacing wires are recommended in this setting.

The manufacturer of the IV preparation (Pfizer, New York) reports in the product literature a series of 61 children receiving amiodarone, of whom 36% had hypotension, 20% had bradycardia, and 15% had atrioventricular block. These complications were severe or life-threatening in some cases. In the published case series of children, the incidence of adverse effects appears to be much lower. In a series reported by Etheridge et al., two of six patients who received intravenously administered amiodarone experienced hypotension.[286] In several other series, the incidence of hypotension ranged from 0 of 15 to 4 of 40.[285,287,289] All patients who were believed to require treatment responded to a saline solution infusion or calcium. One patient with symptomatic bradycardia responded to temporary pacing. Two other patients required a reduction in the rate of drug infusion for mild bradycardia.

Noncardiac adverse effects are often seen, especially with chronic dosing.[292] The most serious adverse effect is the development of interstitial pneumonitis, seen most often in patients with preexisting lung disease.[293] The incidence in children is unknown. Rarely an acute respiratory distress syndrome–like illness has been reported in both infants and adults at the initiation of treatment.[294,295] The lung disease may remit with early discontinuation of the drug. Thyroid disorders may occur with chronic use. Desethylamidarone, the major metabolite of amiodarone, appears to have an antithyroid effect by noncompetitive binding to the nuclear receptors. Both hyperthyroidism with thyrotoxicosis and hypothyroidism have occurred. This may be of particular concern in the management of fetal tachycardias. Although amiodarone appears to be effective in controlling refractory life-threatening fetal tachycardias, evidence of fetal hypothyroidism was present in 19% of neonates based on cord blood thyroid-stimulating hormone.[296] Other forms of toxicity include hepatotoxicity that may progress to cirrhosis, photosensitivity and skin discoloration, and local inflammation and cellulitis at the infusion site. Injection site reactions occurred in 5 of 20 patients who received amiodarone through a peripheral IV line. Corneal opacities are a common finding with chronic therapy but apparently do not affect vision.

The published data on amiodarone use in pediatric cardiac arrest is sparse; its use is derived mostly from adult experiences and animal studies.[297,298] A case series of 40

pediatric patients with ventricular, atrial, or junctional tachyarrhythmias established the safety and efficacy of the drug in critically ill patients.[289] Subsequent to the publication of the 2015 AHA guidelines, Valdes et al. examined the use of amiodarone and lidocaine in in-hospital pediatric patients with pulseless VT or VF. They found that lidocaine was independently favorably associated with ROSC and 24-hour survival, but not survival to hospital discharge. However, amiodarone did not have any association with survival outcomes.[3] This led to the inclusion of lidocaine as a first line antiarrhythmic alongside amiodarone for pulseless VT and VF in the 2015 AHA guideines.[189]

Lidocaine is a Vaughn-Williams class Ib agent that inhibits fast inward sodium current, primarily affecting the ventricular myocardium, and produces a decrease in automaticity. Cells in the sinoatrial and atrioventricular node are minimally affected. It is highly selective for depressed myocardial tissue. Proarrhythmic effects are relatively uncommon, though high plasma concentrations are associated with depressed myocardial function especially in patients with underlying poor myocardial function. The half-life is 5 to 10 minutes, though hypokalemia can decrease its effect. The loading dose is 1 mg/kg, with an infusion rate of 20 to 50 mcg/kg/min. Since this agent does not increase the QTc interval, its use is preferable to amiodarone in patients with a prolonged QTc.

Procainamide is a Vaughn-Williams class Ia agent that slows the upstroke of the action potential by blocking sodium channels. This slows conduction in atrial and ventricular muscle cells and suppresses normal and abnormal automaticity. Procainamide increases the PR interval and the QRS duration and prolongs the QTc interval. Amiodarone and ranitidine increase procainamide levels. The IV bolus dose is 10 to 15 mg/kg, and a continuous infusion of 30 to 80 mcg/kg/min may be used. High doses have a negative inotropic effect and caution should be exercised in patients with a prolonged QT interval, left ventricular dysfunction, or sinus dysfunction. The risk of proarrhythmia, especially torsades de pointes, is moderate and not related to serum drug concentrations.

Postresuscitation Care

Hemodynamic instability is common after cardiac arrest. A persistently low cardiac index may lead to multiorgan failure and is associated with early death within the first 24 hours after arrest.[299,300] Systolic hypotension in the 6 hours after a pediatric cardiac arrest has also been found to be associated with in-hospital mortality and worse neurologic outcomes.[301] Therapies to address low cardiac output states have included the use of inodilators. Inodilators (inamrinone and milrinone) augment cardiac output with little effect on myocardial oxygen demand. An inodilator can be used to treat myocardial dysfunction with increased systemic or pulmonary vascular resistance.[302,303] Administration of fluids may be required because of the vasodilatory effects. Inodilators have a long half-life with a long delay in reaching a new steady-state hemodynamic effect after changing the infusion rate (18 hours with inamrinone and 4.5 hours with milrinone). In case of toxicity, adverse effects may persist for several hours after the infusion is discontinued.

Amelioration of neurologic injury after cardiac arrest has been a goal of many investigators over the past decades (Box 41.3). Two multicenter trials on mild hypothermia after cardiac arrest, one from Europe and the other from Australia,

showed initial promise. In both studies, adult patients presenting with out-of-hospital VF who were resuscitated underwent rapid cooling to a target temperature between 32.8°C and 34.8°C. This temperature was maintained for 12 to 24 hours. Both neurologic outcome and mortality were improved compared with the control groups. The odds ratio for improved neurologic outcome was 1.4 in the European study, which included 275 patients, and 5.25 in the Australian study, which included 77 randomized patients. The hypothermia groups had lower mean blood pressure, required more frequent use of epinephrine, and had higher systemic vascular resistance.

Experimental Cerebroprotective Therapy

- Calcium channel blockers
- Glutamate receptor antagonists
- Opiate receptor antagonists
- Central α_2-receptor antagonists
- β-Receptor antagonists
- Oxygen radical scavengers
- Iron chelators
- Xanthine oxidase inhibitors
- Inhibitors of arachidonic acid metabolism
- Thrombolytic agents
- Lazeroids
- Cerebral vasodilators
- Metabolic activators/inhibitors
- Hypothermia
- Nitric oxide synthase inhibitors
- Adenosine agonists
- Antiplatelet agents
- Antineutrophil strategies
- Protease inhibitors

• Growth factors

Criticisms of these trials have included that they have a limited generalizability and that the control groups were not temperature controlled to avoid hyperthermia, which is known to worsen neurologic outcomes.[304,305] To that end, the Targeted Temperature Management trials sought to further investigate if mild hypothermia conferred any benefit over a controlled normothermia.[306] The trial compared temperature maintenance at 33°C versus 36°C in unconscious adult survivors of the entire out-of-hospital cardiac arrest patient population, regardless of the reason for arrest. The trial showed no difference in survival between the two groups, nor in the secondary outcome of survival and neurologic outcome. Subsequent studies evaluating targeted temperature management did not find differences in the systemic inflammatory response or cognitive outcome at 6 months between the 33°C and 36°C groups.[307-309]

The Therapeutic Hypothermia after Pediatric Cardiac Arrest (THAPCA) trials sought to evaluate mild hypothermia versus controlled normothermia in unconscious children suffering from out-of-hospital cardiac arrest.[11] Eligible patients between the age of 48 hours and 18 years were randomized to mild hypothermia (target temperature of 33.0°C) or therapeutic normothermia (36.8°C). No difference between survival or functional outcome was found at 1 year. A trial of targeted temperature management in children after in-hospital cardiac arrest is currently being conducted.

Future Directions

Despite the aforementioned therapeutic advances, continued efforts to clarify their applicability to infants and children are vital. Clinical trials have been hampered by the federal regulation known as the "final rule" for resuscitation research.[310] In 1996, as part of a broad-ranging effort to protect patients' rights as human subjects, the standard of community consent for research that required immediate intervention was developed. Since that time, resuscitation research in both adults and children has been limited, with most trials conducted in Europe, Australia, and other countries, often with US collaborators. The feasibility of defining a community standard to perform a hypothetical trial of hypothermia after cardiac arrest in children was tested in 2004.[311] The relevant community was defined as hospital staff and the parents of ICU patients and parents of previously resuscitated children. They concluded that development of a study using an exemption from informed consent was feasible. However, in an accompanying editorial, Moler reiterates that, despite feasibility, practicality is very different as evidenced by the complete lack of pediatric resuscitation trials since 1996.[299,310] Whether revision of this rule will occur or techniques for acquiring community consent can be developed remains one of the major hurdles to future pediatric resuscitation research.

CHAPTER 42

Performance of Cardiopulmonary Resuscitation in Infants and Children

Robert M. Sutton, Robert A. Berg, Vinay M. Nadkarni

PEARLS

- The four distinct phases of cardiac arrest and cardiopulmonary resuscitation (CPR) are as follows:

1. Prearrest
2. No flow (untreated cardiac arrest)
3. Low flow (CPR)
4. Postresuscitation

- The most common precipitating event for cardiac arrests in children is respiratory insufficiency; adequate ventilation and oxygenation are high priority.
- High-quality CPR (ie, push hard, push fast, allow full chest recoil, minimize interruptions, and do not overventilate) can improve cardiac arrest outcomes.
- Real-time monitoring and feedback combined with reflective debriefings of team performance can improve CPR quality and survival outcomes.
- Attention to meticulous postresuscitation care, specifically blood pressure and targeted temperature management, can improve survival outcomes.
- Strategically focused therapies to specific phases of cardiac arrest and resuscitation can lead to more successful resuscitation in children.

Pediatric cardiac arrest is not a rare event. Approximately 16,000 American children (8-20/100,000 children/year) experience cardiopulmonary arrest each year.[1–7] Approximately half of these cardiac arrests occur in the hospital and about half

outside the hospital.[5,8] In times past, survival outcomes were not good and many children had severe neurologic injury after their arrest event. With advances in resuscitation science and implementation techniques, survival from pediatric cardiac arrest has improved substantially since the 1990s.[9,10] This chapter focuses on pediatric cardiac arrest, cardiopulmonary resuscitation (CPR), and other therapeutic interventions that have been specifically designed to improve outcomes from pediatric cardiac arrest.

Four Phases of Cardiac Arrest

The four distinct phases of cardiac arrest and CPR interventions are (1) prearrest, (2) no flow (untreated cardiac arrest), (3) low flow (CPR), and (4) postresuscitation. Interventions to improve the outcome of pediatric cardiac arrest should optimize therapies targeted to the time and phase of CPR, as suggested in Table 42.1.

TABLE 42.1

Phases of Cardiac Arrest and Targeted Interventions

Phase	Interventions
Prearrest phase: *Protect*	Optimize community education regarding child safety Optimize patient monitoring Prioritize interventions to prevent progression to cardiac arrest Early recognition and activation of medical emergency response teams
Arrest (no-flow): *Preserve*	Minimize interval to BLS and ACLS phase Organized 911/code blue response system Preserve cardiac and cerebral substrate Minimize interval to defibrillation, when indicated
Low-flow (CPR): *Resuscitate*	Effective CPR to optimize myocardial blood flow and cardiac output Avoid overventilation Consider adjuncts to improve vital organ perfusion during CPR Match oxygen delivery to oxygen demand Consider extracorporeal CPR if standard CPR/ALS are not promptly successful
Postresuscitation: *Regenerate* Short term	Optimize cardiac output and cerebral perfusion Treat arrhythmias, if indicated Prevent hyper/hypoglycemia, hyperthermia Consider mild resuscitative systemic hypothermia
Long term	Early intervention with occupational and physical therapy Bioengineering and technology interface rehabilitation Possible future role for stem cell transplantation

ACLS, advanced cardiovascular life support; *ALS*, advanced life support; *BLS*, basic life support; *CPR*, cardiopulmonary resuscitation.

Prearrest

The prearrest phase refers to relevant preexisting conditions of the child (eg, sepsis, pulmonary hypertension, neurologic, cardiac, respiratory, or metabolic problems) and precipitating events (eg, respiratory failure, hypotensive shock, pulmonary hypertension). It is known that pediatric patients who suffer an in-hospital cardiac arrest often have changes in their physiologic status in the hours leading up to their arrest event.[11–14] Therefore interventions during the prearrest phase focus on preventing the cardiac arrest, with special attention to early recognition and treatment of respiratory failure and shock. Rapid response teams or medical emergency teams (METs) are in-hospital emergency teams designed specifically for this purpose. These teams respond to patients on general inpatient units who are at

high risk of clinical decompensation and transfer these children to more acute care areas, with the goal to prevent progression to full cardiac arrest. Implementation of pediatric METs has been moderately successful; decreased cardiac arrest frequency and mortality have been demonstrated.[13–18] Although METs cannot identify all children at risk for cardiac arrest, it seems reasonable to assume that transferring critically ill children to an intensive care unit (ICU) early in their disease process for better monitoring and more aggressive interventions can improve resuscitative care and clinical outcome.

No Flow/Low Flow

To improve outcomes from pediatric cardiac arrest, it is imperative to shorten the no-flow phase of untreated cardiac arrest. To that end, it is important to monitor high-risk patients to allow early recognition of the cardiac arrest and initiate basic and advanced life support. Effective CPR optimizes coronary perfusion pressure and cardiac output to critical organs to support vital organ viability during the low-flow phase. Important tenets of basic life support are push hard, push fast, allow full chest recoil between compressions, and minimize interruptions of chest compression. Achieving optimal coronary perfusion pressure, exhaled carbon dioxide concentration, and cardiac output during the low-flow phase of CPR is consistently associated with an improved chance for the return of spontaneous circulation (ROSC) and improved short- and long-term outcome in both animal and human studies.[19–29] For ventricular fibrillation (VF) and pulseless ventricular tachycardia (VT), rapid detection and prompt defibrillation are vital for successful resuscitation. For cardiac arrests resulting from asphyxia or ischemia, provision of adequate myocardial perfusion and myocardial oxygen delivery are most important.

Postresuscitation

The postresuscitation phase includes management of the immediate postresuscitation stage, the next few hours to days, hospital course, and long-term rehabilitation and reintegration to the community. The immediate postresuscitation stage is a high-risk period for ventricular arrhythmias and critical organ (eg, heart, brain, kidney) reperfusion injuries. Interventions during the immediate postresuscitation stage and the next few days include delivering adequate tissue oxygen, treating postresuscitation myocardial dysfunction, and minimizing postresuscitation tissue injury (eg, preventing postresuscitation hyperthermia, targeting temperature management, targeting blood pressure management, avoiding hyperglycemia/hypoglycemia, recognizing and promptly treating seizures, and preventing secondary organ injury). This postarrest phase may have the greatest potential for innovative advances in the understanding of cell injury and death, inflammation, mitochondrial dysfunction and recovery, apoptosis, and hibernation, ultimately leading to novel interventions. The rehabilitation stage concentrates on salvaging injured cells, recruiting hibernating cells, and reengineering reflex and voluntary communications of these cell and organ systems to improve functional outcome.

The specific phase of resuscitation dictates the focus of care. Interventions that improve outcome during one phase may be deleterious during another. For instance,

intense vasoconstriction during the low-flow phase of cardiac arrest improves coronary perfusion pressure and the probability of ROSC. The same intense vasoconstriction during the postresuscitation phase increases left ventricular afterload and may worsen myocardial strain and dysfunction. Current understanding of the physiology of cardiac arrest and recovery allows us to only crudely manipulate blood pressure, oxygen delivery and consumption, body temperature, and other physiologic parameters in our attempts to optimize outcome. Future strategies likely will take advantage of increasing knowledge of cellular inflammation, thrombosis, reperfusion, mediator cascades, cellular markers of injury and recovery, and transplantation technology.

An overview of some of the pathophysiologic pathways perturbed by cardiac arrest and resuscitation, along with potential avenues for intervention, is shown in Fig. 42.1.

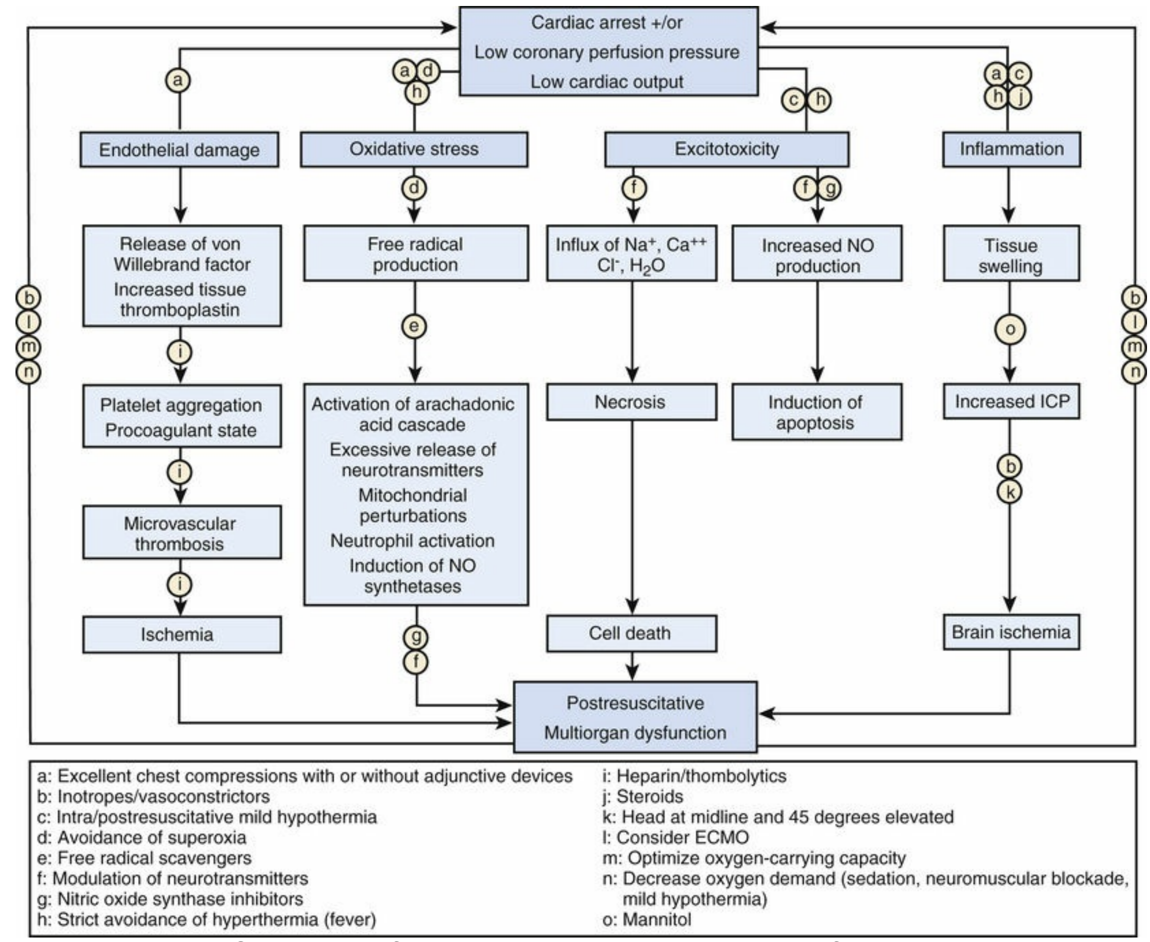

FIG. 42.1 Schematic of physiologic processes that result from cardiac arrest and initial resuscitation, with some promising interventions indicated by lowercase letters. Many complex interconnections and feedback loops among these processes are omitted from the schematic in order to generate an overview of the processes and potential interventions.

Epidemiology of Pediatric Cardiac Arrest

Cardiovascular disease remains the most common cause of disease-related death in the United States, resulting in approximately 1 million deaths per year.[30,31] It is estimated that more than 400,000 Americans will have a cardiac arrest each year, more than 50% in prehospital settings. Although data regarding the incidence of childhood cardiopulmonary arrest are less robust, the best data suggest that about 16,000 American children suffer a cardiac arrest each year (annual incidence: 8 to 20 per 100,000 children per year).[1–5,32–34] For in-hospital arrests specifically, it is estimated that approximately 1.4% of all children admitted to pediatric intensive care units[1,2,8,35] and 4% to 6% of children admitted to cardiac units will suffer a cardiac arrest.[36–40] In short, pediatric cardiac arrest is an important public health problem.

Outcomes from pediatric cardiac arrest have improved significantly since the 1990s. More than 70% of children who have an in-hospital cardiac arrest are successfully resuscitated initially (ie, attain sustained ROSC). Moreover, more than 35% of them will survive to hospital discharge, and many (nearly 75%) will have good neurologic function.[1–4,9,37–39,41–76] Factors that influence outcome from pediatric cardiac arrest include (1) the preexisting condition of the child, (2) the initial electrocardiographic (ECG) rhythm detected, (3) the duration of no-flow time (the time during an arrest when there is no spontaneous circulation or provision of CPR), and (4) the quality of the life-supporting therapies provided during the resuscitation. With this knowledge, it is no surprise then that out-of-hospital pediatric arrests have worse outcomes compared to in-hospital arrests.[3,32,35,44,49,52,55,59,61,77–83] As many of these out-of-hospital events are not witnessed and bystander CPR is not common (approximately 30% to 40% of children receive bystander CPR),[3,84] the duration of no-flow time can be prolonged. As a result, less than 10% of these children survive their initial event, and neurologic injury is common in those who do survive. These findings are especially troublesome given that bystander CPR more than doubles patient survival rates.[85]

Compared to adults, superior survival rates are documented after pediatric cardiac arrest, specifically after in-hospital events; 27% of children survive to hospital discharge compared with only 17% of adults.[9] These findings may be due in part to differences in the initial ECG rhythm detected. Although pediatric arrests are less commonly caused by arrhythmias, such as ventricular tachycardia or ventricular fibrillation (10% of pediatric arrests versus 25% of adult arrests), the superior pediatric survival rate reflects a substantially higher survival rate among children with asystole or pulseless electrical activity compared with adults (24% versus 11%). Moreover, the higher survival rate seen in children is mostly attributable to a much better survival rate among infants and preschool-age children compared with older children.[86,87] Although this is speculative, the higher survival rates in children may be due to improved coronary and cerebral blood flow during CPR because of increased chest compliance in these younger arrest victims.[88,89]

Interventions During the Low-Flow Phase: Cardiopulmonary Resuscitation

Airway and Breathing

During the low-flow state of CPR, cardiac output and pulmonary blood flow are approximately 25% of that during normal sinus rhythm; therefore much less ventilation is necessary for adequate gas exchange from the blood traversing the pulmonary circulation. Moreover, animal and adult data indicate that a rapid rate of assisted ventilation (overventilation from exuberant rescue breathing) during CPR is common and can substantially compromise venous return and cardiac output by increasing intrathoracic pressure.[90–92] Moreover, these detrimental hemodynamic effects are compounded when one considers the effect of interruptions in CPR to provide airway management and rescue breathing.[93–98] Although overventilation is problematic, in light of the fact that most pediatric arrests are asphyxial in nature, provision of *adequate* ventilation is still important. The difference between arrhythmogenic and asphyxial arrests lies in the physiology.[27,28,99,100] In animal models of sudden VF cardiac arrest, acceptable PaO_2 and $PaCO_2$ persist for 4 to 8 minutes during chest compressions without rescue breathing.[101] This is in part because aortic oxygen and carbon dioxide concentrations at the onset of the arrest do not vary much from the prearrest state. As a result, the lungs act as a reservoir of oxygen during CPR, and adequate oxygenation and ventilation can continue without rescue breathing. However, during asphyxial arrest, blood continues to flow to tissues in the prearrest state, resulting in significant arterial and venous oxygen desaturation, elevated lactate levels, and depletion of the pulmonary oxygen reserve. Therefore at the onset of resuscitation, the arterial hypoxemia and acidemia are substantial. In this circumstance, rescue breathing with controlled ventilation can be lifesaving. In contrast, the adverse hemodynamic effects from overventilation during CPR combined with the interruptions in chest compressions to open the airway and deliver rescue breathing are lethal in certain circumstances such as VT/VF arrests. In short, the resuscitation technique should be titrated to the physiology of the patient to optimize patient outcome.

Circulation

Optimizing Blood Flow During Low-Flow Cardiopulmonary Resuscitation: Push Hard, Push Fast

When the heart arrests and no blood flows to the aorta, coronary blood flow ceases immediately.[102] At that point, the provision of high-quality CPR (push hard, push fast) is necessary to reestablish flow. The goal during CPR is to maximize the myocardial perfusion pressure (MPP), as related by the following equation:

$$\begin{aligned} \text{MPP} = {} & \text{Aortic diastolic blood pressure (AoDP)} - \\ & \text{Right atrial pressure (RAP)} \end{aligned}$$

Myocardial blood flow improves as the gradient between AoDP and RAP increases. During the downward compression phase, aortic pressure rises at the same time as right atrial pressure with little change in the MPP. However, during the decompression phase of chest compressions, the right atrial pressure falls faster and lower than the aortic pressure, which generates a pressure gradient perfusing the

heart with oxygenated blood during this artificial period of “diastole.” Several animal and human studies have demonstrated in both VT/VF and asphyxial models the importance of establishing MPP as a predictor for short-term survival outcome (ROSC).[25,103–109]

Based on the preceding equation, MPP can be improved by strategies that increase the pressure gradient between the aorta and the right atrium. As an example, the inspiratory impedance threshold device (ITD) is a small, disposable valve that can be connected directly to the tracheal tube or facemask to augment negative intrathoracic pressure during the inspiratory phase of spontaneous breathing and the decompression phase of CPR by impeding airflow into the lungs. Application in animal and adult human trials of CPR has established the ability of the ITD to improve vital organ perfusion pressures and myocardial blood flow[93,110–113]; however, in a randomized trial during adult CPR, mortality benefit was limited to the subgroup of patients with pulseless electrical activity, and the quality of CPR was an important confounding factor.[114–117] Additional evidence that augmentation of negative intrathoracic pressure can improve perfusion pressures during CPR comes from the active compression-decompression device (ACD). The ACD is a handheld device that is fixed to the anterior chest of the victim by means of suction—think household plunger—that can be used to apply active decompression forces during the release phase, thereby creating a vacuum within the thorax. By actively pulling during the decompression phase, blood is drawn back into the heart by the negative pressure.[118] Animal and adult studies have demonstrated that the combination of ACD with ITD acts in concert to further improve perfusion pressures during CPR compared to ACD alone.[111] In the end, although novel interventions such as the ITD and ACD are promising to improve blood flow during CPR, the basic tenants of “push hard, push fast, minimize interruptions, and do not overventilate” are still the dominant factors to improve blood flow during CPR and advance the chance of survival.

Chest Compression Depth

The pediatric chest compression depth recommendation of at least one-third anterior-posterior chest depth (approximately 4 cm in infants and 5 cm in children) is largely based on expert clinical consensus, using data extrapolated from animal, adult, and limited pediatric data. Maher and colleagues published data from a case series of infants postcardiac surgery associating arterial blood pressure with qualitative chest compression depths. In this small study of six infants, chest compressions targeted to one-half anterior-posterior chest depth improved systolic blood pressures compared to those at one-third anterior-posterior chest depth.[119] Though a small series with qualitatively estimated chest compression depths, this is the first study to collect actual data from children supporting the existing chest compression depth guidelines. On the contrary, two studies using computer-automated tomography[120,121] suggest that depth recommendations based on a relative (%) anterior-posterior chest compression depth are deeper than those recommended for adults, and that a one-half anterior-posterior chest depth is unattainable in most children. A report of 87 pediatric resuscitation events, most involving children >8 years, found that a compression depth >51 mm for more than 60% of the compressions during 30-second epochs within the first 5 minutes of cardiac arrest was associated with improved survival.[122] Thus the 2015 International

Liaison Committee on Resuscitation (ILCOR) consensus on science and American Heart Association (AHA) guidelines recommend a compression depth of at least one-third the anterior-posterior diameter of the chest for children (birth to onset of puberty), which equates to approximately 1.5 inches (4 cm) in infants and 2 inches (5 cm) in children.[123,124] Once children reach puberty, a depth of at least 5 cm, but no more than 6 cm, is recommended. Future studies that collect data from actual children and that associate quantitatively measured chest compression depths with short- and long-term clinical outcomes (arterial blood pressure, end-tidal carbon dioxide, return of spontaneous circulation, survival) are needed.

Compression/Ventilation Ratios

The amount of ventilation provided during CPR should match, but not exceed, perfusion and should be titrated to the amount of circulation during the specific phase of resuscitation as well as the metabolic demand of the tissues. Therefore during the low-flow state of CPR when the amount of cardiac output is roughly 25% of normal, less ventilation is needed.[125] However, the best ratio of compressions to ventilations in pediatric patients is largely unknown and depends on many factors including the compression rate, the tidal volume, the blood flow generated by compressions, and the time that compressions are interrupted to perform ventilations. Evidence has demonstrated that a compression/ventilation ratio of 15 : 2 delivers the same minute ventilation and increases the number of delivered chest compressions by 48% compared to CPR at a compression/ventilation ratio of 5 : 1 in a simulated pediatric arrest model.[126,127] This is important because when chest compressions cease, the aortic pressure rapidly decreases and coronary perfusion pressure falls rapidly.[102] Increasing the ratio of compressions to ventilations minimizes these interruptions, thus increasing coronary blood flow. These findings are in part the reason the 2015 AHA guidelines recommend a pediatric compression/ventilation ratio of 15 : 2.

Duty Cycle

In a model of human adult cardiac arrest, cardiac output and coronary blood flow are optimized when chest compressions last for 30% of the total cycle time (approximately 1 : 2 ratio of time in compression to time in relaxation).[128] As the duration of CPR increases, the optimal duty cycle may increase to 50%. In a juvenile swine model, a relaxation period of 250 to 300 milliseconds (duty cycle of 40% to 50% at a compression rate of 120/min) correlates with improved cerebral perfusion pressures compared with shorter duty cycles of 30%.[129]

Circumferential Versus Focal Sternal Compressions

In adult and animal models of cardiac arrest, circumferential (vest) CPR has been demonstrated to improve CPR hemodynamics dramatically.[130] In smaller infants, it is often possible to encircle the chest with both hands and depress the sternum with the thumbs while compressing the thorax circumferentially (thoracic squeeze). In an infant animal model of CPR, this two-thumb method of compression with thoracic squeeze resulted in higher systolic and diastolic blood pressures and a higher pulse pressure than traditional two-finger compression of the sternum.[131]

Open-Chest Cardiopulmonary Resuscitation

Excellent standard closed-chest CPR generates cerebral blood flow that is approximately 25% of normal. By contrast, open-chest CPR can generate cerebral blood flow that approaches normal. Whereas open-chest massage improves coronary perfusion pressure and increases the chance of successful defibrillation in animals and humans,[132–134] performing a thoracotomy to allow open-chest CPR is impractical in many situations. A retrospective review of 27 cases of CPR following pediatric blunt trauma (15 with open-chest CPR and 12 with closed-chest CPR) demonstrated that open-chest CPR increased hospital cost without altering rates of ROSC or survival to discharge. However, survival in both groups was 0%, indicating that the population may have been too severely injured or too late in the process to benefit from this aggressive therapy.[135] Earlier institution of open-chest CPR may warrant reconsideration in selected special resuscitation circumstances.

Medications Used to Treat Cardiac Arrest

Although animal studies have indicated that epinephrine can improve initial resuscitation success after both asphyxial and VF cardiac arrests, no single medication has been shown to improve survival outcome from pediatric cardiac arrest. A variety of medications are used during pediatric resuscitation attempts including vasopressors (epinephrine or vasopressin), antiarrhythmics (amiodarone or lidocaine), and other drugs such as calcium chloride and sodium bicarbonate. Each is discussed separately next.

Vasopressors

Epinephrine (adrenaline) is an endogenous catecholamine with potent α- and β-adrenergic stimulating properties. The α-adrenergic action (vasoconstriction) increases systemic and pulmonary vascular resistance. The resultant higher aortic diastolic blood pressure improves coronary perfusion pressure and myocardial blood flow even though it reduces global cardiac output during CPR. The adequacy of myocardial blood flow is a critical determinant of ROSC. Epinephrine also increases cerebral blood flow during CPR because peripheral vasoconstriction directs a greater proportion of flow to the cerebral circulation.[136–138] However, evidence suggests that epinephrine can decrease local cerebral microcirculatory blood flow at a time when global cerebral flow is increased.[139] The β-adrenergic effect increases myocardial contractility and heart rate and relaxes smooth muscle in the skeletal muscle vascular bed and bronchi; however, the β-adrenergic effects are not observed in the peripheral vascular beds secondary to the high dose used in cardiac arrest. Epinephrine also increases the vigor and intensity of VF, boosting the likelihood of successful defibrillation. One study showed that among children with in-hospital cardiac arrest with an initial nonshockable rhythm who received epinephrine, delay in the administration of epinephrine >5 minutes from time of cardiac arrest was associated with a decreased chance of survival to hospital discharge with a favorable neurologic outcome.[140]

High-dose epinephrine (0.05–0.2 mg/kg) improves myocardial and cerebral blood flow during CPR more than standard-dose epinephrine (0.01–0.02 mg/kg) in animal models of cardiac arrest and may increase the incidence of initial ROSC.[141,142]

Administration of high-dose epinephrine, however, can worsen a patient's postresuscitation hemodynamic condition. Retrospective studies indicate that use of high-dose epinephrine in adults or children may be associated with a worse neurologic outcome.[143,144] A randomized, controlled trial of rescue high-dose epinephrine versus standard-dose epinephrine following failed initial standard-dose epinephrine in pediatric in-hospital cardiac arrest demonstrated a worse 24-hour survival in the high-dose epinephrine group (1/27 versus 6/23, $p < .05$).[145] Based on these clinical data, high-dose epinephrine cannot be recommended routinely for either initial or rescue therapy.[146]

Vasopressin is a long-acting endogenous hormone that acts on specific receptors to mediate systemic vasoconstriction (V_1 receptor) and reabsorption of water in the renal tubule (V_2 receptor). The vasoconstriction is most intense in the skeletal muscle and skin vascular beds. Unlike epinephrine, vasopressin is not a pulmonary vasoconstrictor. In experimental models of cardiac arrest, vasopressin increases blood flow to the heart and brain and improves long-term survival compared with epinephrine. However, vasopressin can decrease splanchnic blood flow during and following CPR and can increase afterload in the postresuscitation period.[147–151] Adult randomized controlled trials suggest that outcomes are similar after the use of vasopressin or epinephrine during CPR.[152,153] During pediatric arrest, a case series of four children who received vasopressin during six prolonged cardiac arrest events suggested that the use of bolus vasopressin may result in ROSC when standard medications have failed.[154] However, a more recent retrospective study of 1293 consecutive pediatric arrests from the National Registry of CPR (NRCPR) found that vasopressin use, though infrequent (administered in only 5% of events), was associated with a lower likelihood of ROSC. Therefore it is unlikely that vasopressin will replace epinephrine as a first-line agent in cases of pediatric cardiac arrest. However, the available data suggest that its use in conjunction with epinephrine may deserve further investigation.

Calcium

Calcium is used frequently in cases of cardiac arrest, despite the lack of evidence for efficacy when it is administered routinely during resuscitation attempts. In the absence of a documented clinical indication (ie, hypocalcemia, calcium channel blocker overdose, hypermagnesemia, or hyperkalemia), administration of calcium does not improve outcome from cardiac arrest.[51,155–163] To the contrary, three pediatric studies have suggested a potential for harm, as routine calcium administration was associated with decreased survival rates or worse neurologic outcomes.[51,155,156]

Buffer Solutions

There are no randomized controlled studies in children examining the use of sodium bicarbonate for management of pediatric cardiac arrest. Two randomized controlled studies have examined the value of sodium bicarbonate in the management of adult cardiac arrest[164] and in neonates with respiratory arrest in the delivery room.[165] Neither was associated with improved survival. One multicenter retrospective in-hospital pediatric study found that sodium bicarbonate administered during cardiac arrest was associated with decreased survival, even after controlling for age, gender, and first documented cardiac rhythm.[155] Therefore during pediatric cardiac arrest

resuscitation, the routine use of sodium bicarbonate is *not* recommended.

Clinical trials involving critically ill adults with severe metabolic acidosis did not demonstrate a beneficial effect of sodium bicarbonate on hemodynamics despite correction of acidosis.[166,167] However, the presence of severe acidosis may depress the action of catecholamines, so the use of sodium bicarbonate may be considered in an acidemic child who is refractory to catecholamine administration.[168,169] Acidosis may increase the threshold for myocardial stimulation in a patient with an artificial cardiac pacemaker[170]; therefore administration of bicarbonate or another buffer is appropriate for management of severe documented acidosis in these children. Administration of sodium bicarbonate also is indicated in the patient with a tricyclic antidepressant overdose, hyperkalemia, hypermagnesemia, or sodium channel blocker poisoning. The buffering action of bicarbonate occurs when a hydrogen cation and a bicarbonate anion combine to form carbon dioxide and water. If carbon dioxide is not effectively cleared through ventilation, its buildup counterbalances the buffering effect of bicarbonate. Because carbon dioxide readily penetrates cell membranes, intracellular acidosis may increase without adequate ventilation. Therefore bicarbonate should not be used to manage respiratory acidosis.

Unlike sodium bicarbonate, tromethamine (THAM) buffers excess protons without generating carbon dioxide. Carbon dioxide is consumed following THAM administration. In a patient with limited ventilation, tromethamine may be preferable when buffering is necessary. Tromethamine undergoes renal elimination, and renal insufficiency may be a relative contraindication to its use. Carbicarb, an equimolar combination of sodium bicarbonate and sodium carbonate, is another buffering solution that generates less carbon dioxide than sodium bicarbonate. In a canine model of cardiac arrest comparing animals given normal saline, sodium bicarbonate, THAM, or Carbicarb, the animals given any buffer solution had a higher rate of ROSC than the animals given normal saline. In the animals given sodium bicarbonate or Carbicarb, the interval to ROSC was significantly shorter than in animals given normal saline. However, at the end of the 6-hour study period, all resuscitated animals were in a deep coma, so no inferences regarding meaningful survival can be drawn.[171] The AHA does not recommend either THAM or other alternatives over bicarbonate when a buffering agent is desired during CPR.[146]

Postresuscitation Interventions

Targeted Temperature Management

Hyperthermia following cardiac arrest is common in children, and fever following cardiac arrest is associated with poor neurologic outcome.[172,173] Two seminal articles addressing adult out-of-hospital VF cardiac arrest have established that mild induced hypothermia (32°C-34°C) is a clinically promising goal-directed postresuscitation therapy. In these randomized studies of comatose patients older than 18 years after VF cardiac arrest, outcomes were improved.[174,175] However, extrapolation of these findings to the pediatric arrest victim is difficult, as fever, trauma, stroke, and other ischemic conditions, common in pediatric cardiac arrest, are associated with poor neurologic outcome. Neonatal trials of selective brain cooling and systemic cooling show promise in neonatal hypoxic-ischemic encephalopathy, suggesting that induced hypothermia may improve outcomes.[176,177] Using an approach of *therapeutic normothermia* with scheduled administration of

antipyretic medications and the use of external cooling devices may be necessary to prevent hyperthermia in this population.

A large multicenter, prospective, randomized study of children aged 2 days to 18 years who remained comatose after out-of-hospital cardiac arrest (OHCA) found a strong trend of 20% versus 12% survival with favorable neurologic outcome, but no significant difference in survival with good functional outcome at 1 year and no additional complications in comatose patients who were treated with therapeutic hypothermia (32°C-34°C), compared to those treated with normothermia (36°C-37.5°C). Additional observational data of children resuscitated from either in-hospital cardiac arrest (IHCA) or OHCA[178–180] have suggested that ICU duration of stay, neurologic outcomes, and mortality are not improved with therapeutic hypothermia. However, one small study of therapeutic hypothermia in survivors of pediatric asphyxia cardiac arrest[181] showed an improvement in survival to hospital discharge, but without a significant difference in neurologic outcome. At the time of publication, results are pending from a large multicenter randomized controlled trial of targeted temperature management for pediatric patients with IHCA (Therapeutic Hypothermia After Cardiac Arrest website: www.THAPCA.org). Thus the AHA states that for infants and children remaining comatose after OHCA, it is reasonable either to maintain 5 days of continuous normothermia (36°C-37.5°C) or to maintain 2 days of initial continuous hypothermia (32°C-34°C) followed by 3 days of continuous normothermia. Continuous measurement of temperature during this time period is recommended and fever (temperature 38°C or higher) should be aggressively treated.[182]

Glucose Control

Both hyperglycemia and hypoglycemia following cardiac arrest are associated with worse neurologic outcome.[183–186] Although it seems intuitive that hypoglycemia would be associated with worse neurologic outcome, whether hyperglycemia per se is harmful or is simply a marker of the severity of the stress hormone response from prolonged ischemia is not clear. In critically ill adult patients, tight glucose control using an insulin infusion was associated with improved survival.[187,188] However, subsequent studies of nonsurgical adult populations and neonatal/pediatric trials have demonstrated no survival benefit or the potential for harm when rates of inadvertent hypoglycemia were high during treatment.[186,189–196] Using the available data, there is insufficient evidence to formulate a strong recommendation on the management of hyperglycemia in children with ROSC following cardiac arrest. If hyperglycemia is treated following ROSC in pediatric patients, blood glucose concentrations should be carefully monitored to avoid hypoglycemia.

Blood Pressure Management

Compared with healthy volunteers, adults resuscitated from cardiac arrest have impaired autoregulation of cerebral blood flow.[197] Hence they may not maintain adequate cerebral blood flow in the context of low systemic pressure and, likewise, may not be able to protect the brain from excessive blood flow and microvascular perfusion pressure in the context of systemic hypertension. However, in animal models, briefly induced hypertension following resuscitation improves neurologic outcome compared with normotensive reperfusion.[198,199] Therefore a practical

approach to blood pressure management following cardiac arrest is to attempt to minimize blood pressure variability in this high-risk period following resuscitation. Three small observational studies after pediatric IHCA and OHCA[200–202] demonstrated worse survival to hospital discharge when children exhibited hypotension after ROSC. One of these studies associated post-ROSC hypotension (defined as a systolic blood pressure less than the fifth percentile for age) after IHCA with a lower likelihood of survival to discharge with favorable neurologic outcome. In 2015, the AHA recommended that a systolic blood pressure >5 percentile for age be maintained. Continuous arterial blood pressure monitoring is recommended to rapidly identify and effectively treat hypotension.[202,203]

Postresuscitation Myocardial Dysfunction

Postarrest myocardial stunning and arterial hypotension occur commonly after successful resuscitation in both animals and humans.[174,175,204–211] Animal studies demonstrate that postarrest myocardial stunning is a global phenomenon with biventricular systolic and diastolic dysfunction. This postarrest myocardial stunning is pathophysiologically and physiologically similar to sepsis-related myocardial dysfunction and post–cardiopulmonary bypass myocardial dysfunction, including increases in inflammatory mediators and nitric oxide production.[204,206,207,210] Because cardiac function is essential to reperfusion following cardiac arrest, management of postarrest myocardial dysfunction may be important to improving survival. The classes of agents used to maintain circulatory function (ie, inotropes, vasopressors, and vasodilators) must be carefully titrated during the postresuscitation phase to the patient's cardiovascular physiology. Trials in animal models have shown that various vasoactive medications can effectively ameliorate postarrest myocardial dysfunction (eg, dobutamine, milrinone, levosimendan).[212–216] Similarly, in human observational studies, fluid resuscitation and various vasoactive medications (ie, epinephrine, dobutamine, and dopamine) have been provided for myocardial dysfunction syndrome.[174,175,205–209,217,218] In the end, optimal use of these agents involves close goal-directed titration, and the use of invasive hemodynamic monitoring may be appropriate.

Other Considerations

Quality of Cardiopulmonary Resuscitation

The quality of health care provider CPR during adult resuscitations typically does not comply with American Heart Association clinical practice guidelines. Long CPR-free intervals, shallow chest compressions, incorrect chest compression rates, and overventilation are common.[219,220] The quality of CPR performed during the resuscitation attempt is directly related to patient outcome.[94,221,222] Studies have shown in adults and in children that patients with a witnessed cardiac arrest[4] and those who receive bystander CPR[223] have an increased chance of survival. Those who suffer their in-hospital cardiac arrest at night or during weekends (presumably when the quality of resuscitation is not as good as in the daytime or on weekdays) have higher mortality.[224] Furthermore, pediatric outcomes are improved in hospitals staffed with highly trained pediatric-specific providers.[32] Taken together, these

findings establish that the quality of resuscitative care, specifically early high-quality CPR, is an important determinate of patient survival.

In an effort to improve CPR quality, CPR-monitoring defibrillators with audiovisual feedback have been used during adult resuscitation, and CPR quality and clinical outcomes have improved.[222,225] The combination of focused bedside training and automated feedback defibrillators improved CPR guideline compliance of in-hospital providers.[226] However, there were still significant portions of the resuscitation that suffered from substandard resuscitative care. The addition of environmental debriefings has been demonstrated to improve short- and long-term outcomes following cardiac arrest in the ICU.[227]

Extracorporeal Membrane Oxygenation Cardiopulmonary Resuscitation

Venoarterial extracorporeal membrane oxygenation (ECMO) has been increasingly used as a rescue therapy during CPR, especially for potentially reversible acute postoperative myocardial dysfunction or arrhythmias. Studies of extracorporeal CPR (E-CPR) have demonstrated favorable early survival outcomes in children with primary cardiac disease when E-CPR protocols were in place at the time of the arrest.[45,228–239] Interestingly, data have been mixed regarding the relationship between outcome and CPR duration before ECMO cannulation. CPR and ECMO are not curative treatments. They are simply cardiopulmonary supportive measures that restore tissue perfusion until the patient has recovered from the precipitating disease process. As such, they can be powerful tools. Thus E-CPR should be considered for children with cardiac arrest who have heart disease amenable to recovery or transplantation, if the arrest occurs in a highly supervised environment such as an intensive care unit with existing clinical protocols and available expertise and equipment to rapidly initiate extracorporeal life support (ECLS).

Ventricular Fibrillation and Ventricular Tachycardia in Children

Pediatric VF or VT has been an underappreciated pediatric problem. Reports indicate that VF and VT (ie, shockable rhythms) occur in 27% of in-hospital cardiac arrests at some time during the resuscitation.[42] In a population of pediatric cardiac intensive care unit patients, as many as 41% of arrests were associated with VF or VT.[36] According to the NRCPR database, during in-hospital arrest, 10% of children had an initial rhythm of VF/VT. In all, 27% of the children had VF/VT at some time during the resuscitation.[42] The incidence of VF varies by setting and age.[240] In special circumstances, such as tricyclic antidepressant overdose, cardiomyopathy, status post–cardiac surgery, and prolonged QT syndromes, VF and pulseless VT are more likely.

The treatment of choice for short-duration VF is prompt defibrillation. In general, the mortality rate increases by 7% to 10% per minute of delay to defibrillation. Because VF must be considered before defibrillation can be provided, early determination of the rhythm by electrocardiography is critical. An attitude that VF is rare in children can be a self-fulfilling prophecy with a uniformly fatal outcome. The

recommended defibrillation dose is 2 J/kg, but the data supporting this recommendation are not optimal and are based on old monophasic defibrillators. In the mid-1970s, authoritative sources recommended starting doses of 60 to 200 J for all children. Because of concerns for myocardial damage and animal data suggesting that shock doses ranging from 0.5 to 1 J/kg were adequate for defibrillation in a variety of species, Gutgesell and colleagues evaluated the efficacy of their strategy to defibrillate with 2 J/kg monophasic shocks. Seventy-one transthoracic defibrillations in 27 children were evaluated. Shocks within 10 J of 2 J/kg resulted in successful defibrillation in 91% of defibrillation attempts. The major determinant of successful defibrillation other than VF duration is countershock current. This current depends on the defibrillator energy and transthoracic impedance. Studies in children indicate that the transthoracic impedance of infants and children greatly overlap. Although there is a statistically significant correlation between size and transthoracic impedance, the correlation is weak. These studies provide only weak support for the present dogma that the defibrillator energy dose should vary directly with weight. Although the limited data regarding pediatric defibrillation used monophasic waveform shocks, most modern defibrillators use biphasic waveform shocks. Defibrillation with these biphasic waveforms is theoretically safer and more effective than monophasic waveform defibrillation. Therefore the use of 2 to 4 J/kg biphasic waveform shocks should be at least as effective as 2 to 4 J/kg monophasic shocks and possibly safer.

Antiarrhythmic Medications: Lidocaine and Amiodarone

The administration of antiarrhythmic medications should not delay the administration of shocks to a patient with VF. However, after an unsuccessful attempt at electrical defibrillation, medications to increase the effectiveness of defibrillation should be considered. Epinephrine is the current first-line medication for both pediatric and adult patients in VF. If epinephrine and a subsequent repeat attempt to defibrillate are unsuccessful, lidocaine or amiodarone should be considered.

Lidocaine traditionally has been recommended for shock-resistant VF in adults and children. In one study, amiodarone improved survival to hospital admission (but not hospital discharge) in the setting of adult shock-resistant VF compared with placebo.[241] In another study of shock-resistant out-of-hospital VF, patients receiving amiodarone had a higher rate of survival to hospital admission than patients receiving lidocaine.[242] A study of adult shock-resistant VF did not show benefit of either amiodarone or lidocaine compared with placebo, but the drugs were administered late in the course of resuscitation.[243] None of these studies included children. An observational analysis of the American Heart Association Get With the Guidelines-Resuscitation registry showed an association of improved ROSC and short-term survival with lidocaine, and not with amiodarone, for pediatric refractory VF in the in-hospital setting.[244] Because there is moderate experience with amiodarone use as an antiarrhythmic agent in children and because of the adult studies, it is rational to use amiodarone similarly in children with shock-resistant VF/VT. The recommended dosage is 5 mg/kg by rapid intravenous bolus. There are no published prospective or randomized comparisons of antiarrhythmic medications for pediatric refractory VF. Although extrapolation of adult data and

electrophysiologic mechanistic information suggest that amiodarone may be preferable for pediatric shock-resistant VF, the optimal choice is not clear.

Pediatric Automated External Defibrillators

Automated external defibrillators (AEDs) have improved adult survival from VF.[245,246] AEDs are recommended for use in children 8 years or older with cardiac arrest.[247,248] The available data suggest that some AEDs can accurately diagnose VF in children of all ages, but many AEDs are limited because the defibrillation pads and energy dosage are configured for adults. Adapters having smaller defibrillation pads that dampen the amount of energy delivered have been developed as attachments to adult AEDs, allowing their use in children. However, it is important that the AED diagnostic algorithm is sensitive and specific for pediatric VF and VT. Four studies have been conducted demonstrating the accuracy of AEDs to recognize pediatric arrhythmias. Case reports suggest AEDs can be used in children, including infants. The algorithms used by AEDs have high sensitivity and specificity for pediatric arrhythmias and rarely recommended a shock inappropriately. The energy doses delivered by AEDs are high, but they are below the range demonstrated to cause harm in laboratory animal studies of shock toxicity. The diagnostic algorithms from several AED manufacturers have been tested for such sensitivity and specificity and therefore can be reasonably used in younger children.

Summary

Outcomes from pediatric cardiac arrest and CPR appear to be improving. Perhaps the evolving understanding of pathophysiologic events during and after pediatric cardiac arrest and the developing fields of pediatric critical care and pediatric emergency medicine have contributed to these apparent improvements. In addition, exciting breakthroughs in basic and applied science laboratories, such as E-CPR, are on the immediate horizon for study in specific subpopulations of cardiac arrest victims. By strategically focusing therapies to specific phases of cardiac arrest, there is great promise that critical care interventions will lead the way to more successful cardiopulmonary and cerebral resuscitation in children.

SECTION III

Respiratory System

OUTLINE

CHAPTER 43

Structure and Development of the Upper Respiratory System in Infants and Children

Robert H. Chun, Joan C. Arvedson

PEARLS

- The structures of the upper airway undergo extensive changes from infancy through young adulthood. An understanding of the numerous variations, congenital anomalies, and resulting special vulnerabilities of the developing airway and underlying illness should result in improved health outcomes and a lower morbidity rate in children with airway disease.
- The upper and lower respiratory tracts develop separately. Thus there are few coincident congenital anomalies between these two contiguous areas.
- An understanding of possible congenital anomalies of the airway will improve diagnosis and treatments.

The respiratory tract can be divided into the upper or conducting airways and the lower or gaseous exchange airways. For the purposes of this chapter, the trachea down to the carina is included as part of the "upper" or conducting airways. The upper airway shares its development with that of the upper digestive tract, and the lower airway shares its development with the cardiovascular system.

Developmental Anatomy of the Upper Airway

The embryologic development of the nasal cavity, mouth, nasopharynx, and hypopharynx occurs in a separate environment from that of the larynx, trachea, bronchi, and lung parenchyma. Because the upper airway and lower respiratory

tract develop separately, there are few coincident congenital anomalies between these two contiguous but developmentally distinct areas.

The branchial arches derived from the neural crest cells begin to appear during the fourth week of embryogenesis. The branchial arches give rise to formation of the face, neck, nasal cavities, mouth, larynx, pharynx, and striated muscles in the head and neck that are involved in breathing and swallowing. The development of these structures is usually complete by week 14.

The respiratory system, including parts of the larynx, trachea, and lungs, also begins to appear during week 4, when the laryngotracheal groove develops into a diverticulum that subsequently separates from the pharynx. In the fourth and fifth weeks, the longitudinal tracheoesophageal folds fuse, forming the tracheoesophageal septum and dividing the foregut into ventral and dorsal portions. The ventral portion becomes the larynx, trachea, bronchi, and lungs, and the dorsal portion becomes the esophagus. Abnormalities in development of the esophagus and trachea can lead to tracheoesophageal fistula (TEF). A rare but significant tracheoesophageal fistula is the H type that could present with recurrent lower airway disease (Fig. 43.1).

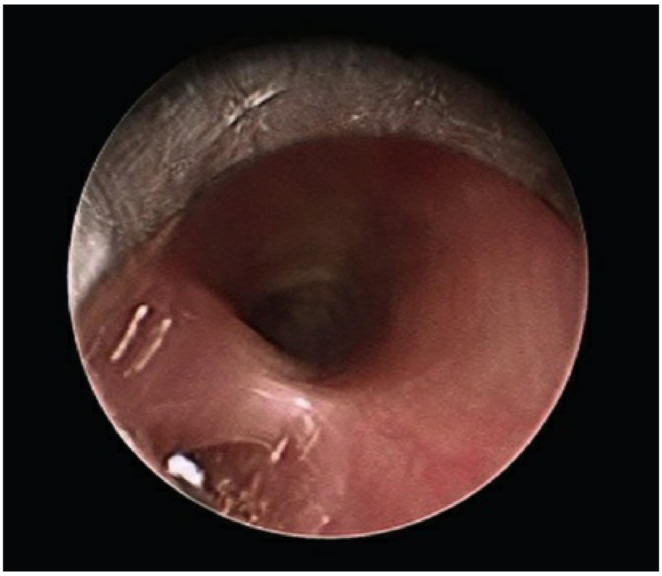

FIG. 43.1 Bronchoscopy with trachea above with tracheoesophageal fistula below.

The embryogenesis of the larynx is complex. The cartilages and muscles are derived from the fourth and sixth branchial arches. The epithelium is derived from the endoderm of the laryngotracheal tube. As this epithelium proliferates rapidly, the larynx is temporarily occluded until the 10th week, when recanalization occurs. Failure to recanalize can result in laryngeal webs, stenosis, or, rarely, atresia (Fig. 43.2). The epiglottis forms by mesenchymal proliferation of the third and fourth branchial arches (Fig. 43.3).

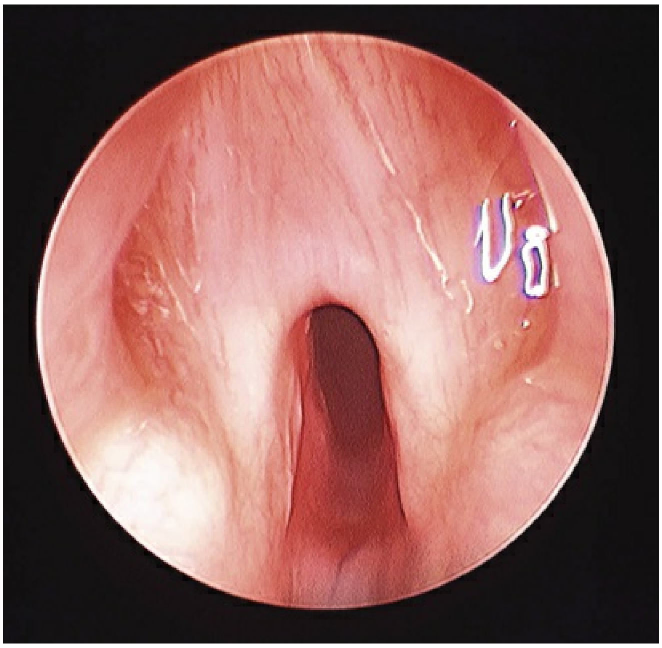

FIG. 43.2 Laryngeal web.

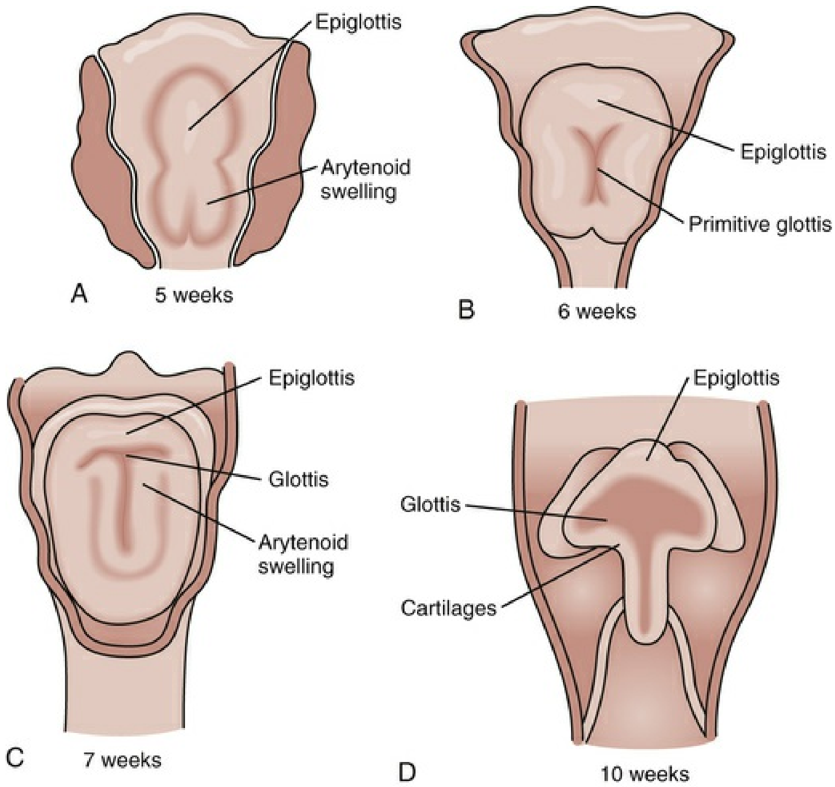

FIG. 43.3 (A–D) Embryologic development of the larynx. (Modified from Arvedson J, Brodsky L. Pediatric Swallowing and Feeding: Assessment and Management. 2nd ed. Boston: Thomson Learning [Cengage Learning]; 2002.)

Another developmental abnormality is a laryngeal cleft that presents as a defect in the posterior arytenoid muscles and sometimes tracheal cartilage leading to aspiration. The cleft can vary from mild to severe depending on the extent of the

defect that may extend from the top of the cricoid cartilage into the thoracic trachea (Fig. 43.4). Findings on videofluoroscopic swallow studies (VFSSs) are suspicious for laryngeal cleft when liquid is seen to move into the trachea posteriorly and lower than typically seen with simple delayed airway closure. Those findings typically lead to further workup to include operative endoscopy with palpation of the larynx, which is the definitive diagnostic procedure.

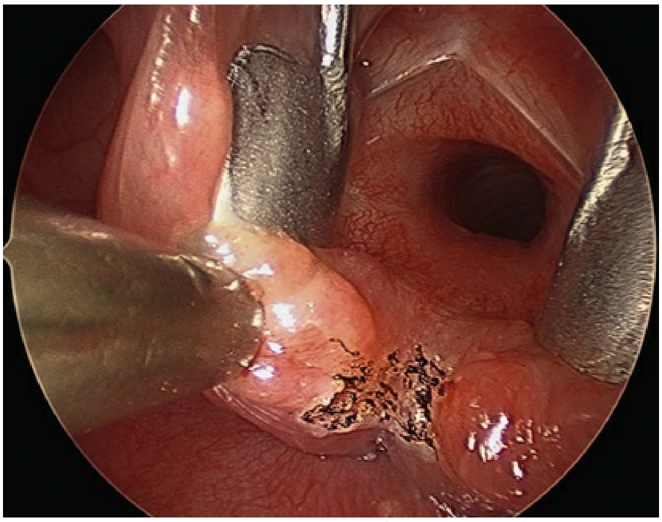

FIG. 43.4 Laryngeal cleft during repair.

The tracheobronchial tree also has several embryonic origins. Its epithelium is derived from the laryngotracheal tube. The connective tissue, cartilages, and muscles are derived from the surrounding splanchnic mesenchyme. All cartilages of the trachea are C-shaped with a membranous posterior tracheal wall, giving the airway flexibility to expand, except for the cricoid cartilage immediately below the true vocal folds. The cricoid cartilage is anatomically considered part of the larynx. It is the only cartilage in the airway to form a complete ring. Because of its inflexibility, edema from intubation and inflammation can result in serious injury that should be avoidable in most cases.

Laryngeal web or subglottic stenosis can present with stridor, likely biphasic, and respiratory distress in a newborn infant (Fig. 43.5). While medical treatment such as steroids, racemic epinephrine, heliox, or intubation may manage these infants in the acute setting, many infants with congenital webs or stenosis will need surgical intervention. Laryngeal atresia that is not diagnosed prenatally will lead to often fatal respiratory distress at birth (Fig. 43.6). The infants' mothers will likely present with severe polyhydramnios and fetal hyperinflation of the lungs. Fetal MRI assists in the diagnosis. A tracheostomy in the newborn period is necessary in coordination with an ex utero intrapartum treatment for airway management.

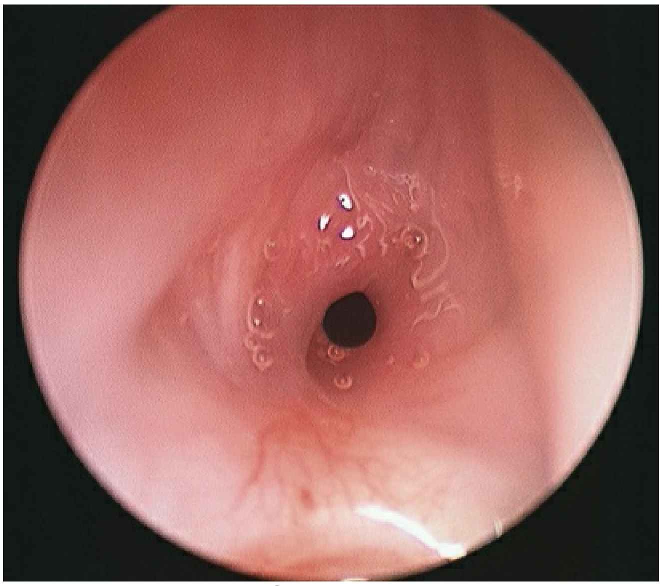

FIG. 43.5 Subglottic stenosis.

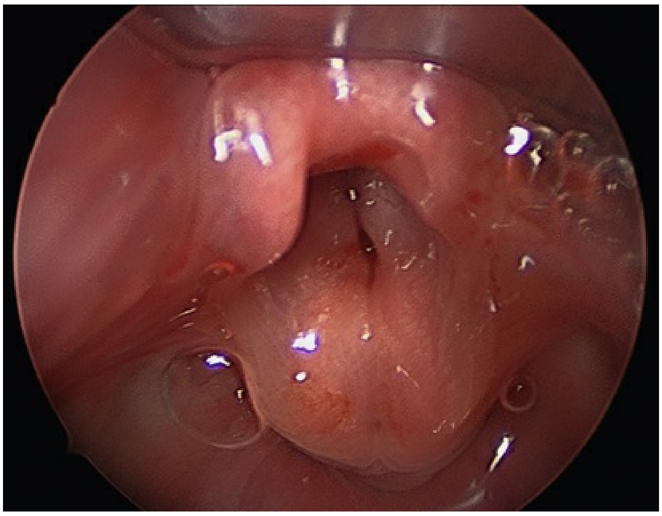

FIG. 43.6 Laryngeal atresia.

Abnormalities of the lower airway can lead to critical airway distress. Although the only normal complete tracheal ring is the cricoid cartilage, complete tracheal rings or tracheal stenosis can lead to difficult intubations and respiratory distress. Depending on the severity of distress and tracheal stenosis, surgical management is needed in the majority of cases (Figs. 43.7 and 43.8). Children with Down syndrome can present with multilevel airway problems as a result of midface hypoplasia, a small nasopharynx, relatively large tongue, and a congenitally narrowed subglottic space. If a child with Down syndrome requires intubation, a smaller endotracheal that is one half size to one full size lower than a child with a normal airway should be used.

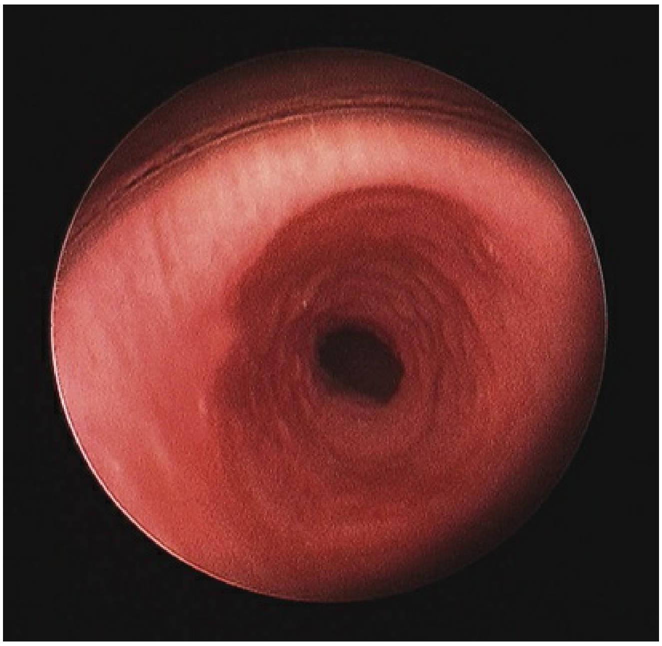

FIG. 43.7 Bronchoscopy demonstrating distal complete tracheal rings.

FIG. 43.8 Congenital tracheal stenosis.

Anatomy and Physiology of the Upper Airway

Nasal Passages

The upper airway begins at the tip of the nose and the vermilion border of the lips. Both the nasal and oral passages allow air to stream from the environment through the larynx into the lungs, where oxygen and carbon dioxide are exchanged in

alveolar-capillary units. Oral passages (oral cavity, oropharynx, and hypopharynx) are conduits for ingestion of the food and liquid needed to support growth and development.

The structures of the upper airways of the infant (Fig. 43.9) gradually change in the first few years of life to assume their adult configuration (Fig. 43.10). Preferential nasal breathing is present in typical term neonates and persists until 6 months of age because of the high position of the larynx in the neck with the soft palate and valleculae in close anatomic approximation. Nasal breathing is a necessary underpinning for nipple feeding at the breast or bottle in order for infants to coordinate sucking, swallowing, and breathing sequencing.

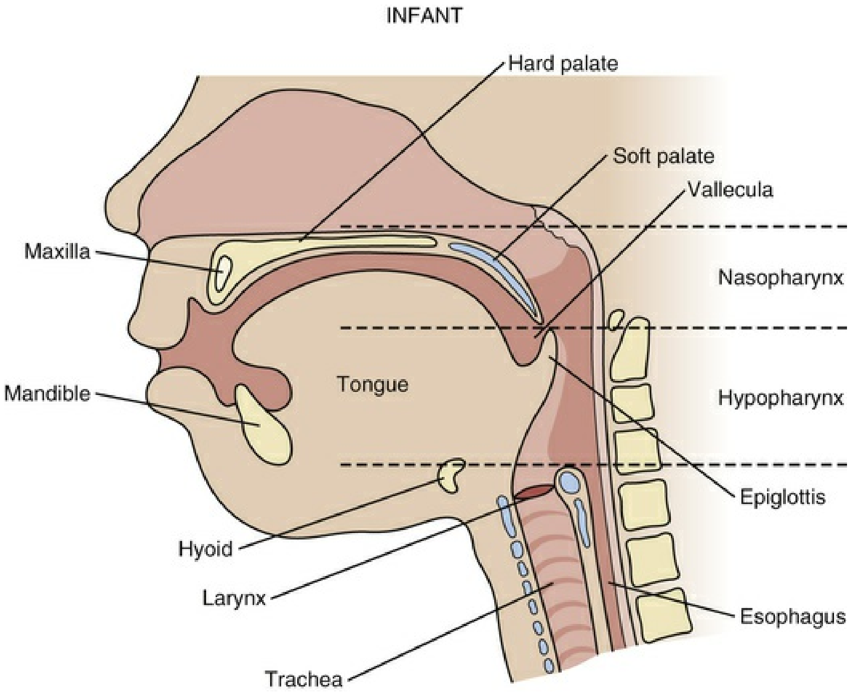

FIG. 43.9 Lateral view of the infant's upper airway. The soft palate and valleculae form a tongue and groove relationship that effectively separates the oral cavity from the nasal cavity during the first 6 months of infancy when most children are primarily nasal breathers. This anatomic proximity effectively separates the oral route for ingestion from the nasal route for respiration. Anterior placement of the larynx has implications for intubation technique. (Modified from Arvedson J, Brodsky L. Pediatric Swallowing and Feeding: Assessment and Management. 2nd ed. Boston: Cengage Learning; 2002.)

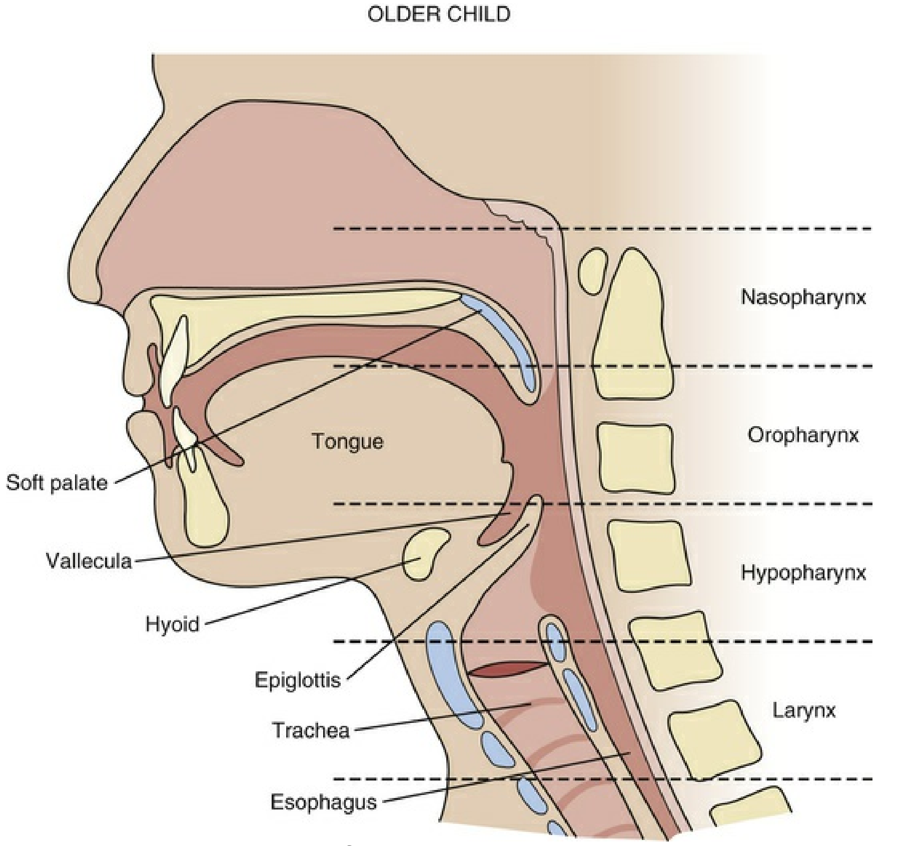

FIG. 43.10 Lateral view of the older child's upper airway. Note the development of the oropharynx, a shared passage for eating and breathing. The tongue occupies less of the oral cavity. The larynx sits lower in the neck, which is unique to humans and has allowed for the development of human speech production. However, the shared passageway with the digestive system creates challenges in airway protection, particularly during intubation. (Modified from Arvedson J, Brodsky L. Pediatric Swallowing and Feeding: Assessment and Management. 2nd ed. Boston: Cengage Thomson Learning; 2002.)

Infants with upper airway obstruction who require enteral feeds are served better with an orogastric (OG) tube than a nasogastric (NG) tube and oxygen delivered by mask rather than by nasal cannula to avoid obstruction and injury to this area. The nasal cavity courses posteriorly to reach the nasopharynx.

The adenoid pad is located in the nasopharynx and sits against the muscles covering the cervical spine at the base of the skull. During the first several years of life, the adenoid may enlarge. In most instances the adenoids involute between age 8 and puberty unless ongoing inflammation occurs as a result of allergy, infection, or gastrointestinal reflux.

In the newborn infant, abnormal development of the nasal cavity can lead to airway obstruction. Pyriform aperture stenosis is an overgrowth of the maxillary crest leading to anterior nasal obstruction. Choanal atresia is a failure of recanalization of the posterior nasopharynx leading to obstruction that may be unilateral or bilateral (Fig. 43.11). An oral airway or intubation can bypass these airway obstructions in an acute setting. Choanal atresia is associated with CHARGE syndrome. Pyriform aperture stenosis is associated with holoprosencephaly, pituitary abnormalities, and central mega incisor syndrome. Therefore

comprehensive genetic and systemic evaluations are critical.

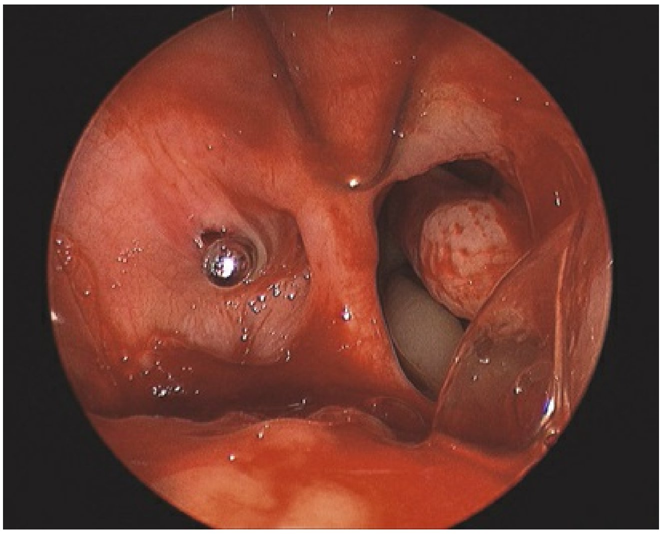

FIG. 43.11 Unilateral choanal atresia undergoing repair. Posterior view.

The nasal passage is divided by the nasal septum, which is cartilaginous anteriorly and bony posteriorly. Injury to the anterior nasal septum is not uncommon with the use of nasal tubes, nasal cannula, or nonhumidified oxygen because of the thin epithelium overlying the cartilage anteriorly. Bacterial colonization frequently occurs when the nasal passages become dry and stasis of secretions occurs. In the critically ill patient, injury to this anterior mucosa can lead to epistaxis. This can be treated with pressure, oxymetazoline, and packing if needed.

The ostia of the paranasal sinuses drain into the nasal cavity. Any obstruction secondary to tubes or inflammation can lead to poor mucus clearance, bacterial overgrowth, and sinusitis. In the critically ill and immunocompromised patient, invasive fungal sinusitis can be a rare but fatal source for fever of unknown origin. Nasal endoscopy and possible biopsy and debridement are needed for evaluation of this disease (Fig. 43.12).

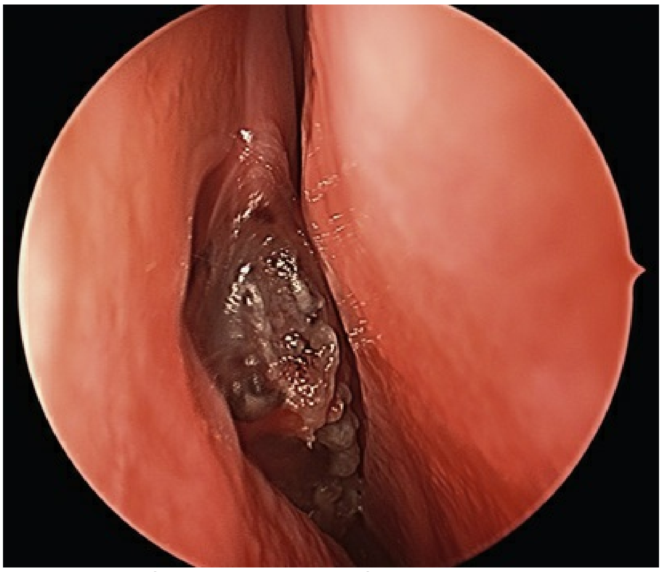

FIG. 43.12 Invasive fungal sinusitis of right necrotic middle turbinate.

Mouth (Oral Cavity) and Pharynx

The structures of the oral cavity include the lips, teeth, tongue, palate, and palatine tonsils. The anterior structures are primarily involved in speech and bolus preparation of food and liquid. The tongue in young infants fills the oral cavity. Children with Beckwith-Wiedemann syndrome have macroglossia. The tongue often protrudes out of the mouth. In some instances, tongue reduction may be necessary or the airway may need to be bypassed. Some craniofacial anomalies are characterized by micrognathia or retrognathia, when even a normal- or smaller-sized tongue may be posteriorly placed, causing upper airway obstruction. Glossoptosis can produce airway obstruction that prevents ventilation by natural or mechanical means. In the critical care setting, an endotracheal tube may be required to bypass the obstruction. Infants with Pierre Robin sequence (micrognathia, glossoptosis, posterior U-shaped cleft palate) may present with severe airway obstruction, especially in supine positioning. Nasal trumpets, oxygen, prone positioning, and intubation may be necessary in the critical setting for airway management. Intubation is difficult with usually a grade 3 to 4 (Cormack and Lehane) laryngeal view. Fiberoptic intubation may be helpful.

The oropharynx that is not seen in young infants begins posterior to the posterior tonsillar pillars with its superior border at the edge of the soft palate and its inferior border at the superior tip of the epiglottis. With growth and development, the pharynx elongates so that an oropharynx can be noted between ages 2 and 3 years. The lateral walls of the pharynx consist of the three pairs of constrictor muscles, which are innervated by cranial nerves V, IX, and X. These cranial nerves provide innervation to muscles that are important in protection of the lower airways. The muscle tone of the pharyngeal constrictors is often compromised in children with neurologic impairment, which may result in airway collapse and obstruction even in the absence of enlarged tonsils and adenoid or glossoptosis. Palatine tonsils are found laterally, and when chronically or severely inflamed, they may enlarge and cause upper airway obstruction similar to that found with enlarged adenoid at the nasopharyngeal level. Often, but not always, enlargement of tonsils and adenoid

occurs together. Hypertrophied palatine tonsils can be noted deep in the pharynx with lateral view VFSS in some children even when the tonsils did not appear markedly enlarged upon visual oral inspection. Hypertrophied tonsils may interfere with bolus transit of solid foods in some children.

The oropharynx is the crossroads for the nasopharynx from above and the hypopharynx from below. Infants have no distinct oropharynx because the nasopharynx is contiguous to the hypopharynx. Lingual tonsil hypertrophy in older children occurs less frequently than hypertrophy of palatine tonsils. Hypertrophy of lingual tonsils may result in airway obstruction or feelings of food getting stuck in the pharynx. When enlarged, they can cause airway obstruction that prevents visualization of the glottis. Vallecular cysts may present in the newborn infant with dysphagia and upper airway obstruction. In some instances, vallecular cysts are associated with acute life-threatening events (Fig. 43.13).

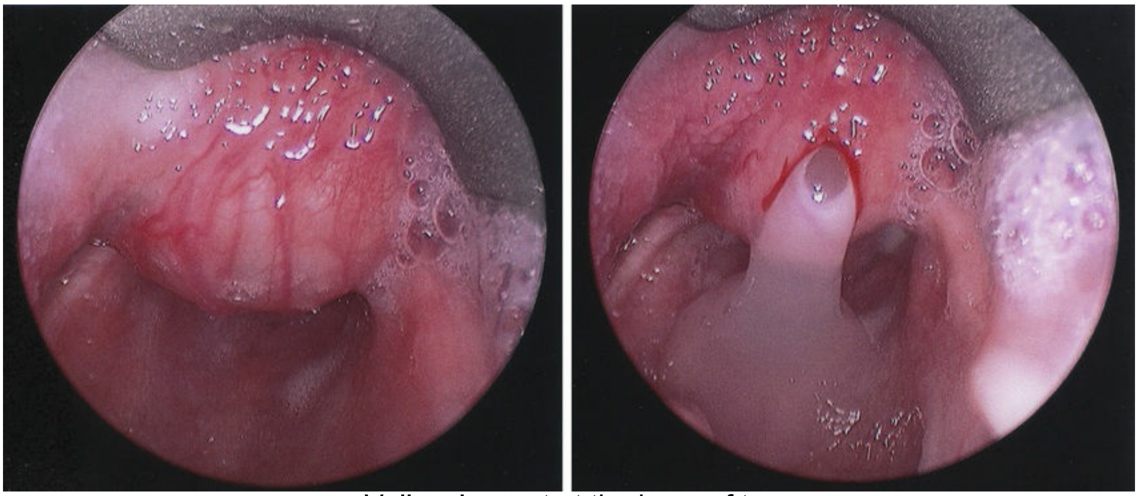

FIG. 43.13 Vallecular cyst at the base of tongue.

The hypopharynx is the most inferior of the shared passageways for respiration and deglutition. Superiorly it is defined by the tip of the epiglottis, which in the adult is at the level of the hyoid bone in the neck, a relationship that is variable in the infant and child. The inferior border of the hypopharynx is at the level of the cricopharyngeus muscle, which is the primary muscle unit in the upper esophageal sphincter located directly posterior to the cricoid cartilage. Protection of the airway occurs in this area, particularly during deglutition. The anterior boundary of the hypopharynx is the larynx. Although immunization has nearly eradicated epiglottitis, toxic-appearing children with stertor, respiratory difficulty, and drooling should still have epiglottis or necrotizing epiglottis in the differential diagnosis (Fig. 43.14). The critical treatment is operative airway management with possibility of tracheotomy.

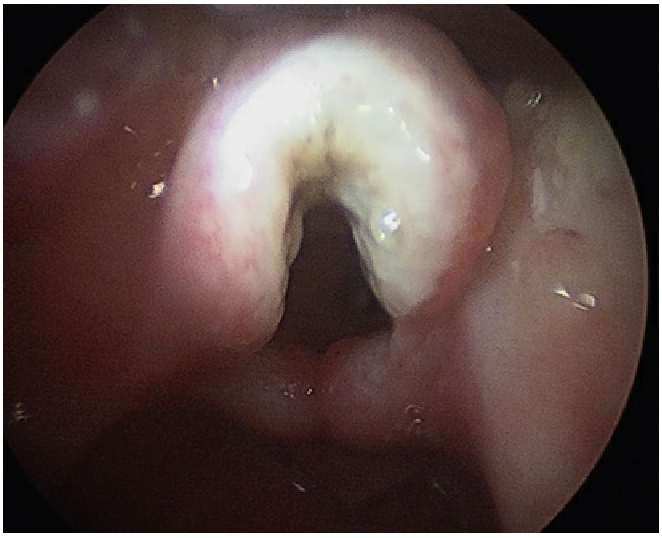

FIG. 43.14 Necrotizing epiglottitis.

Larynx

The larynx is a complex structure of cartilage, ligaments, and muscles involved in respiration, protection of the lower airways, and phonation. The larynx begins at the level of the true vocal folds and extends to the inferior border of the cricoid cartilage.

Proper airflow requires that the larynx have functioning vocal folds so that during inspiration there is abduction of the true vocal folds, allowing the least restrictive inflow of air. During expiration, slight adduction occurs and the false vocal folds (also known as the ventricular folds) modulate the expiratory airflow.

Protection of the lower airways is key to survival. Prevention of aspiration of secretions or ingested food requires multilevel coordination of several sphincters. The most superior level is the epiglottis, which has a flattened lingual surface directing secretions laterally and posteriorly as it folds into the larynx during deglutition. The paired arytenoid cartilages sit at the posterior aspect of the larynx and provide the next level of protection. These cartilages, along with the coordination of the aryepiglottic folds, contract medially to close the glottis. Simultaneously, the larynx is elevated and pulled forward by hyolaryngeal excursion, which provides the airway with further protection during swallowing. Finally, the paired true and false vocal folds adduct and provide yet another level of protection. During quiet respiration, the highly innervated larynx repels unwanted secretions by the highly sensitive cough reflex, mediated primarily through cranial nerves IX and X. In the intubated, often sedated, or paralyzed child, these protective mechanisms are absent and the dangers of aspiration of secretions become of great concern. Frequent suctioning of oral cavity secretions may reduce this risk but is unlikely to eliminate aspiration completely.

Innervation of the larynx for its protective and respiratory functions is located centrally in the brain stem, making it reflexive. The sensory and motor innervations to this area are critical to proper function. Thus following prolonged intubation, immediate return of function is unrealistic. A cautionary approach to the reestablishment of oral feeds is prudent. Another issue to consider is that intubation may cause recurrent laryngeal nerve injury with vocal fold paralysis or paresis. The

mechanism for this injury is believed to result from pressure on the cricoarytenoid joint close to where the nerve enters the larynx.

Children presenting with bilateral vocal fold paralysis should be evaluated for their airway obstruction, as well as for intracranial or thoracic causes of their obstruction, such as an Arnold-Chiari malformation. Unilateral vocal fold paralysis is a known complication following pediatric heart surgery, especially patent ductus arteriosus (PDA) ligation. Spontaneous recovery may occur in 25% to 45% of cases in 1 to 2 years of time. If feeding, voice, and breathing are appropriate, no intervention is required.

Laryngomalacia is a prolapsing of the posterior arytenoid mucosa and foreshortened aryepiglottic folds that cause a spectrum of airway obstruction. Laryngomalacia is characterized by inspiratory stridor, associated airway obstruction, and dysphagia. Most children (>80%) outgrow this condition, but children with sleep apnea, failure to thrive, and pectus excavatum many need further surgical management. Nearly 20% of these children will also have a synchronous airway lesion in the lower airway.

Anatomic differences between the upper aerodigestive tracts of infants and children are listed in Table 43.1.

TABLE 43.1

Anatomic Airway Differences Between Infants and Children

Anatomic Location	Infant	Older Child
Oral cavity	Tongue fills mouth Edentulous Tongue rests between lips and sits against palate Relatively smaller mandible	Mouth is larger, tongue rests on the floor of the mouth Dentulous Tongue rests behind teeth and not against palate Mandibular-maxillary relationship relatively normal
Pharynx	No definite/distinct oropharynx Obtuse angle at skull base in nasopharynx	Elongation from nasopharynx through hypopharynx with distinct oropharynx 90-degree angle at skull base
Larynx/tracheobronchial tree	One-third adult size Half of true vocal fold is cartilage Narrow, vertical epiglottis Subglottis size in a full-term newborn neonate fits a 3.5 uncuffed endotracheal tube Tracheal rings more compliant	Less than one-third of true vocal fold is cartilage Flat, wide epiglottis Subglottis enlarges with age

Modified from Arvedson J, Brodsky L. Pediatric Swallowing and Feeding: Assessment and Management. 2nd ed. Boston: Thomson Learning; 2002.

Trachea and Bronchi

Inferior to the larynx is the trachea. It conducts air to the bronchi, which branch to ever smaller lumen tubes that eventually become alveoli, the anatomic location of gas exchange. The trachea is made of cartilaginous rings that are essentially the same diameter until they reach the carina, where the trachea splits into left and right main stem bronchi.

The right main stem bronchus is shorter, wider, and takes off at a less acute angle than does the left main stem bronchus. Bronchial foreign body aspiration is seen more often in the right main stem bronchus than in the left main stem bronchus. Bronchial intubation is more often encountered on the right. The right main stem

bronchus leads to the right upper, middle, and lower lobes of the lungs.

The left main stem bronchus is longer, narrower, and more acutely angled than the right main stem bronchus. Its bronchi lead to the left lower and upper lobes. As mentioned previously, these airways are lined by pseudostratified, ciliated columnar epithelium. This epithelium is readily injured through suctioning. Prolonged intubation, particularly after tracheotomy, results in diffuse squamous metaplasia. Without functioning cilia, airway secretions remain in the airway and can be the source of irritation, inflammation, and atelectasis, all complicating factors in the management of the upper airway during a critical illness.

Acknowledgment

The authors would like to dedicate the chapter to the memory of Dr. Linda Brodsky.

CHAPTER 44

Structure and Development of the Lower Respiratory System in Infants and Children

John E. Baatz, Rita M. Ryan

PEARLS

- Lungs increase in volume from about 250 mL at birth to 6000 mL in the adult.
- Each lung lobe is subdivided into 19 bronchopulmonary segments, which receive a primary segmental bronchus and a tertiary pulmonary artery branch and are drained by pulmonary veins.
- The airway branching pattern in the lung undergoes multiple generations, yielding a total of 27 or 28 divisions when counting begins from the primary bronchus.
- The aggregate length of the airways in the adult lung spans approximately 1500 miles or 2400 km.
- The bronchial mucosa contains several epithelial cell types with the ciliated cell comprising more than 90% of the epithelial cell population in the conducting airways, but the proportion and number of cilia per cell decrease from the proximal to distal airways.
- The acinus, which is approximately spherical in shape and has a diameter of about 7 mm and a length of 0.5 to 1 cm, is the gas exchange portion of the lung.
- At the alveolar level, many changes occur in the postnatal period. Although there is disparity concerning the time alveolarization is completed, alveoli in a normal adult number from 300 to 500 million and have a diameter of 150 to 200 μm.
- The two epithelial cells of the alveolus are the gas-exchanging type I cell and type II cell, which are responsible for the production of pulmonary surfactant and have a central role in repair.
- The alveolar-capillary unit is composed of three major constituents: epithelial

lining of the alveolus, capillary endothelial cells, and a mixture of cellular and extracellular interstitial components.
- Following birth the pulmonary vasculature undergoes extensive remodeling and, when fully matured, thickness of the pulmonary artery is only about 60% that of the aorta.
- The large pulmonary arteries traverse the lung with the cartilaginous airways and extend from the hilum nearly halfway down the bronchial tree.
- Smaller pulmonary arteries measure between 100 and 1000 μm in diameter, branch with the bronchial tree, and lie close to bronchi and bronchioles.
- Pulmonary veins do not course with the bronchial tree; instead, they are seen within the interlobular septae.

Lower Respiratory System

Overview of the Lungs

While the upper airway of the respiratory system is involved in uptake of air for delivery to the lungs and in the removal of large particulates from the air, the primary purpose of the lower respiratory tract is to efficiently deliver oxygen to the blood and remove expired carbon dioxide. The main components of the lower respiratory tract are the trachea, bronchial tubes, and lungs. The lungs are dense, spongy structures composed of smaller branches of the bronchi called bronchiolar tubes, which, after several branching generations, terminate at alveolar sacs, where oxygen and carbon dioxide are exchanged with the blood of alveolar sac–associated capillaries. The trachea, bronchial tubes, and bronchioles serve to provide rapid delivery of large volumes of air, whereas the alveolar sacs provide the large surface area required for sufficient gas diffusion.

Externally, the lungs are paired structures that, with the mediastinum, fill the thoracic cavity. Normally, the right lung is composed of three lobes and the left lung consists of two lobes and the lingula, arising from the left upper lobe. The lobes are separated by fissures and have hili that receive a primary lobar bronchus, pulmonary artery and veins, bronchial arteries and veins, lymphatics, and nerves (Fig. 44.1).[1,2] The lobes are further subdivided into 19 bronchopulmonary segments that receive primary segmental bronchi, a tertiary pulmonary artery branch and are drained by pulmonary veins. Pulmonary veins do not course with the airway and pulmonary artery; instead, they course midway between the dyads and can be readily identified in the intersegmental septa. The connective tissue septa that demarcate each bronchopulmonary segment define the smallest surgically resectable portions of the lung.

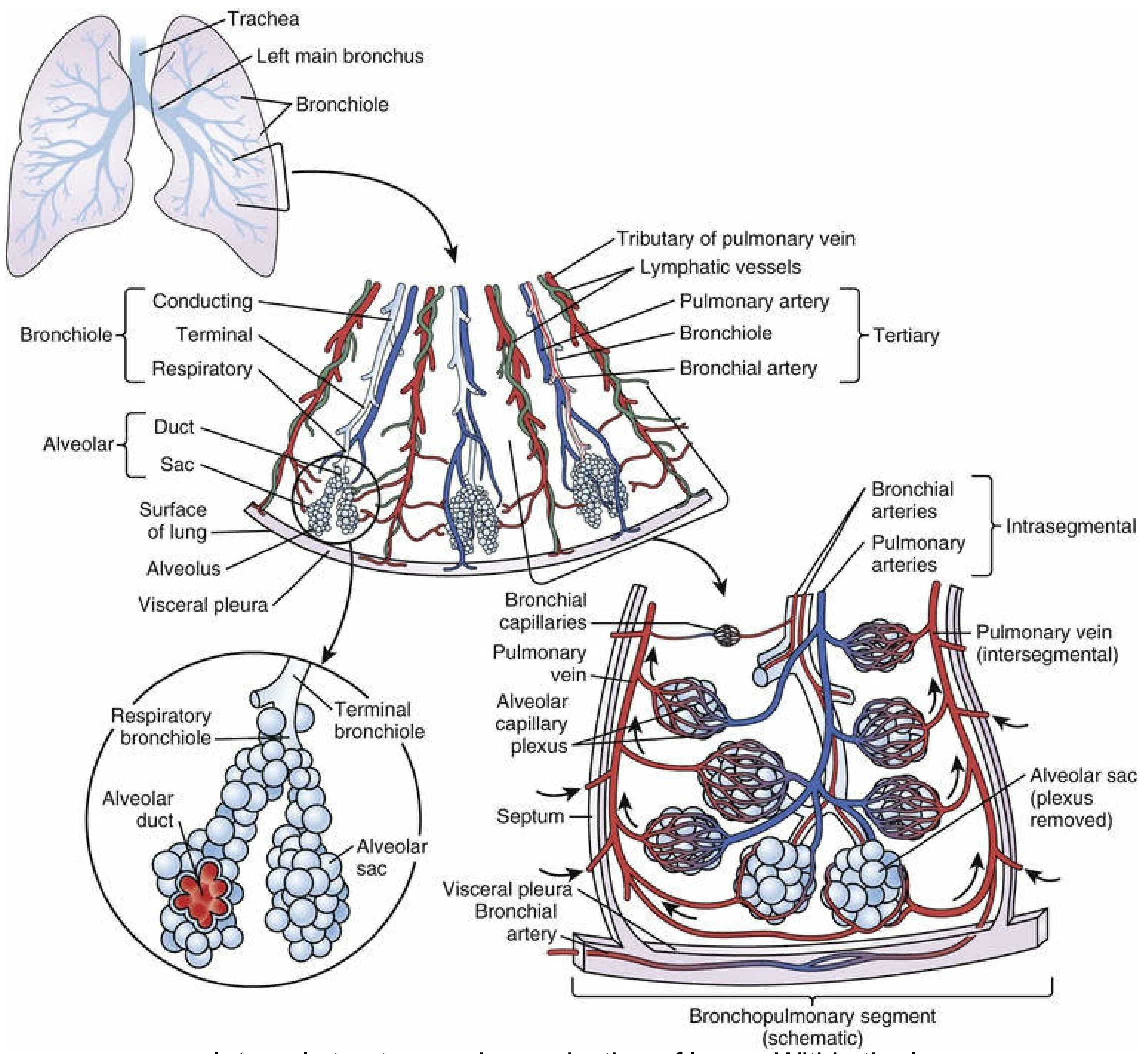

FIG. 44.1 Internal structure and organization of lungs. Within the lungs, the bronchi and pulmonary arteries are paired and branch in unison. Segmental (tertiary) branches supply the bronchopulmonary segments. Each intrasegmental pulmonary artery ends in a capillary plexus in the walls of the alveolar sacs and alveoli. The pulmonary veins arise from the pulmonary capillaries and drain toward and then course within the septa between adjacent segments. Bronchial arteries are distributed along and supply the bronchial tree. Their distal-most branches supply capillary beds drained by the pulmonary veins, such as those of the visceral pleura (even though this small amount of blood is poorly oxygenated). (Modified from Moore KL, Dalley AF. Clinically Oriented Anatomy. 5th ed. Philadelphia: Lippincott Williams & Wilkins; 2006.)

The lung bud develops in the first month of the embryonic period, after which extensive branching progresses (≈20 generations) forming the bronchial tree by mid-second trimester.[3] The most rapid period of human lung development occurs between 22 weeks' gestational age (wga) and term (≈40 wga). This is during the saccular period, when alveolarization is initiated and accelerates, yielding approximately 20,000,000 to 50,000,000 alveoli at birth—only 6% to 16% of that in the full-grown adult lung.[4] The beginning of the third trimester (22-27 wga) is not only critical with respect to premature births but also because early development of fetal human lungs primarily occurs in the presence of fetal hemoglobin ($\alpha_2\gamma_2$), while later stages (~27 wga-~38 wga) of human fetal lung development (which includes

initiation of both pulmonary surfactant expression and accelerated alveolarization) occur during the main γ to β globin transition, ie, from fetal to adult hemoglobin ($\alpha_2\beta_2$).[5-7] Fetal hemoglobin binds oxygen more efficiently than adult hemoglobin, yielding higher oxygen tensions in lung tissue of developing human fetuses. Therefore treatment of premature infants with regard to oxygen delivery should consider potential risks associated with the oxygen-binding properties of the predominant hemoglobin form.

At birth, the lungs weigh about 40 g and double in weight by 6 months. Lung volume increases from about 250 mL at birth to 6000 mL in the adult.[8] Mature respiratory alveoli appear at approximately 36 weeks of gestation and continue to develop until about 2 years of age, with an approximate total surface area of 2.8 m^2. By age 2 years, most of the alveolarization process is completed, but newly formed alveolar septa still contain a double capillary network rather than a single one observed in adult lungs. Therefore over the next several years, the capillary bed will reorganize well after alveolar formation. After 8 years of age, the lung enters the phase of natural growth.[9]

Airways

In the lung, the airway undergoes multiple generations of branching, yielding a total of 23 to 28 divisions when counting begins from the primary bronchus. The bronchi are the larger intrinsic cartilaginous airways and comprise 9 to 12 generations starting with the primary bronchus and terminating in bronchi, having a diameter of approximately 1 mm. Bronchioles, sometimes called *membranous bronchioles* or *distal noncartilaginous airways,* are conducting airways. They comprise an additional 12 generations before ending as terminal bronchioles, the last purely conducting structure in the lung. Horsfield and Cumming showed that the course from the trachea to the alveolar level may comprise as few as 8 or as many as 24 airway branch points.[10] The first 16 generations of branching are genetically determined, while more distal branching and alveolarization are more plastic and are much more likely to be influenced by maternal nutrition and other extrinsic factors.[11] For this reason, a particular airway diameter may be found at various points along the course of the airway. Determination of the total cross section of airways is important in understanding the distribution of airway resistance. Weibel[12] showed that as the peripheral generations of the airways are approached, the total cross-sectional area of the lung is markedly increased, suggesting that peripheral airways account for only a small proportion of total airway resistance. In the adult, an asymmetric dichotomous branching pattern is seen, each daughter branch having a cross-sectional area about 75% of its parent branch. This results in an increase of combined cross-sectional area of the two daughter branches. It is well known, however, that peripheral airway resistance in children's lungs is disproportionately high. The size of the conducting airways is related to stature, so the airways' cross-sectional area in children increases at a slow rate with growth and aging. Because the peripheral airways make up a significant portion of the total respiratory resistance in children, disease in the bronchioles can be serious.

The bronchi maintain the histologic appearance of the trachea in that mucosa, submucosa, muscularis, adventitia, and cartilaginous support are present. As the bronchi branch deeper into the lung parenchyma, the cartilage rings become plates

and less regular, and the muscularis becomes continuous, being located between the submucosa and cartilage plates. Also contained within the bronchial submucosa are mucus-secreting submucosal glands, nerves, ganglia, and bronchial arterial branches (Fig. 44.2). As the bronchi decrease in diameter, the pseudostratified columnar epithelium becomes lower and the mucoserous glands become fewer in number. Although the glands wane in number in the more distal parts of the lung, mucous cells persist and can be found in very small bronchi and some membranous bronchioles.

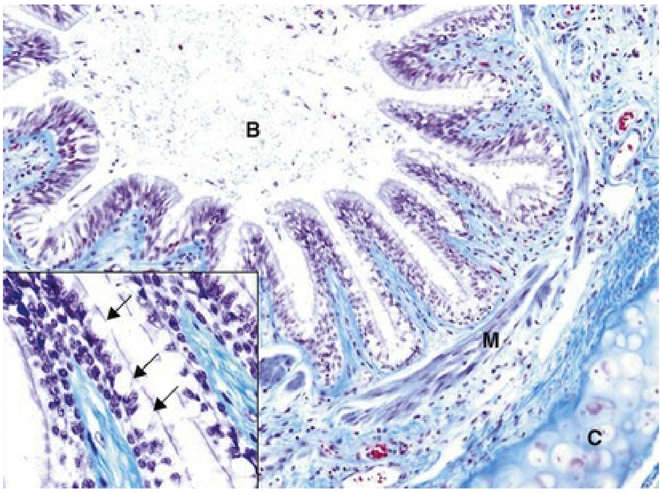

FIG. 44.2 Bronchus *(B)* with surrounding smooth muscle *(M)* and cartilage *(C).* The airway mucosa (inset) is composed of ciliated epithelial cells and vacuolated goblet cells *(arrowheads).* (Gomori trichrome; ×40 and ×400.)

The bronchial mucosa contains several epithelial cell types: ciliated, mucus producing (goblet cells), basal, brush, and neuroendocrine.[13,14] The ciliated cell constitutes more than 90% of the epithelial cell population in the conducting airways, but the proportion and number of cilia per cell decrease from the proximal to distal airways. The 9 + 2 microtubular structure within the cilia has been shown to be altered in the primary ciliary syndromes (Fig. 44.3). In addition to its ciliary beating movement, the ciliated columnar cells regulate the depth of the composition of the periciliary fluid and transport ions across the epithelium. The basal cell has a progenitor cell role and also functions to maintain adherence of columnar cells to the basement membrane. The brush cell, thought to have a role in fluid absorption and/or chemoreceptor function, is found rarely in the tracheobronchial and alveolar epithelia.

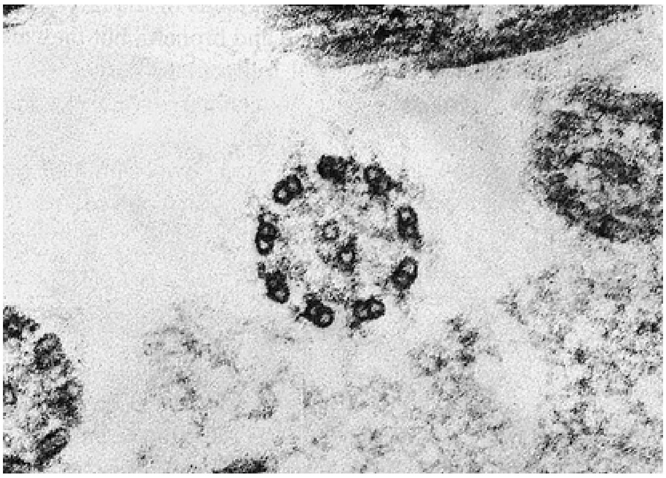

FIG. 44.3 Internal structure of a cilium (no cell membrane evident) in which two axial tubules and nine peripheral duplex tubules are seen. Dynein arms are attached to several of the peripheral duplex tubules (×13,500).

The mucociliary apparatus is the primary defense mechanism in the respiratory system. Although mucous goblet cells secrete mucin, it is the submucosal glands that produce more than 90% of the mucus needed for mucociliary function. The glandular unit of the bronchial submucosa comprises mucous, serous, myoepithelial cells, collecting duct cells, and occasionally neuroendocrine (Kulchitsky) cells.[14,15] The physical characteristics of the mucous layer reveal that the superficial layer is more viscous than the deeper layer. This difference in consistency of the mucous layer allows the cilia to function properly, allowing a power and recovery stroke mechanism. The secretions include lysozyme, antileukoprotease, lactoferrin, and IgA. The secretory component of IgA is synthesized in bronchial gland cells and expressed on their basolateral cell surfaces, to which IgA dimers synthesized by plasma cells bind. The complex is endocytosed by the glandular cell and then is secreted from its luminal surface. Neuroendocrine cells can be solitary near the basal lamina between columnar cells or in collections called *neuroepithelial bodies* that occur near branch points of bronchi.[15] The neuroendocrine cells are more abundant in the fetus and likely have a role in lung growth or maturation.

Although originally defined as having a lumen diameter less than 2 mm, the term *small airway* usually refers to a bronchiole. Histologically, the bronchiole is characterized by a transition from pseudostratified tall columnar epithelium to a more cuboidal ciliated form. In addition, the mucous goblet cell is replaced by the nonciliated Clara cell (Figs. 44.4 and 44.5). In the bronchiolar epithelium, a ratio of about three ciliated cells to two nonciliated cells lines the lower airways. The Clara cell is identified as a dome- or tongue-shaped cell that protrudes into the bronchiolar lumen among the shorter ciliated cells. The Clara cell has varying features according to species but possesses an abundance of agranular reticulum and secretory granules. Clara cells synthesize and secrete Clara cell secretory protein (CC10, CC16), a unique 10-kDa protein similar to rabbit uteroglobin that has antiinflammatory and immunoregulatory functions.[16] In addition, Clara cells secrete surfactant-associated proteins A, B, and D. Importantly, the Clara cell also functions as a progenitor cell that differentiates into ciliated cells following injury, and some investigators have shown that the Clara cell can differentiate into a type II epithelial

cell.[17]

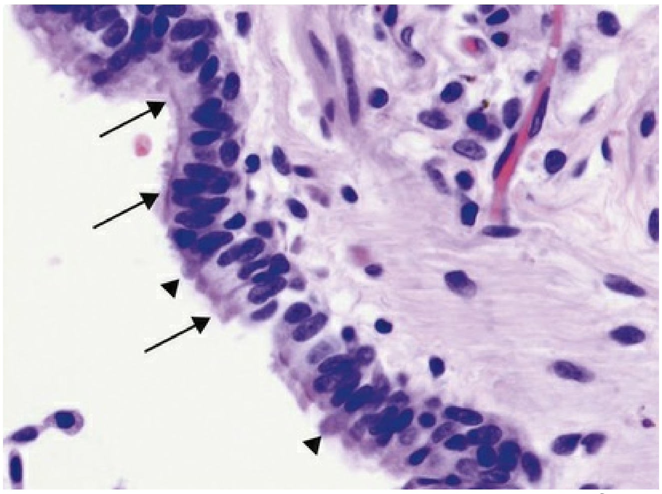

FIG. 44.4 Distal conducting airway mucosa composed of some ciliated epithelial cells showing a terminal bar *(arrows)* and a nonciliated Clara cell *(arrowheads).* (Hematoxylin-eosin stain; ×400.)

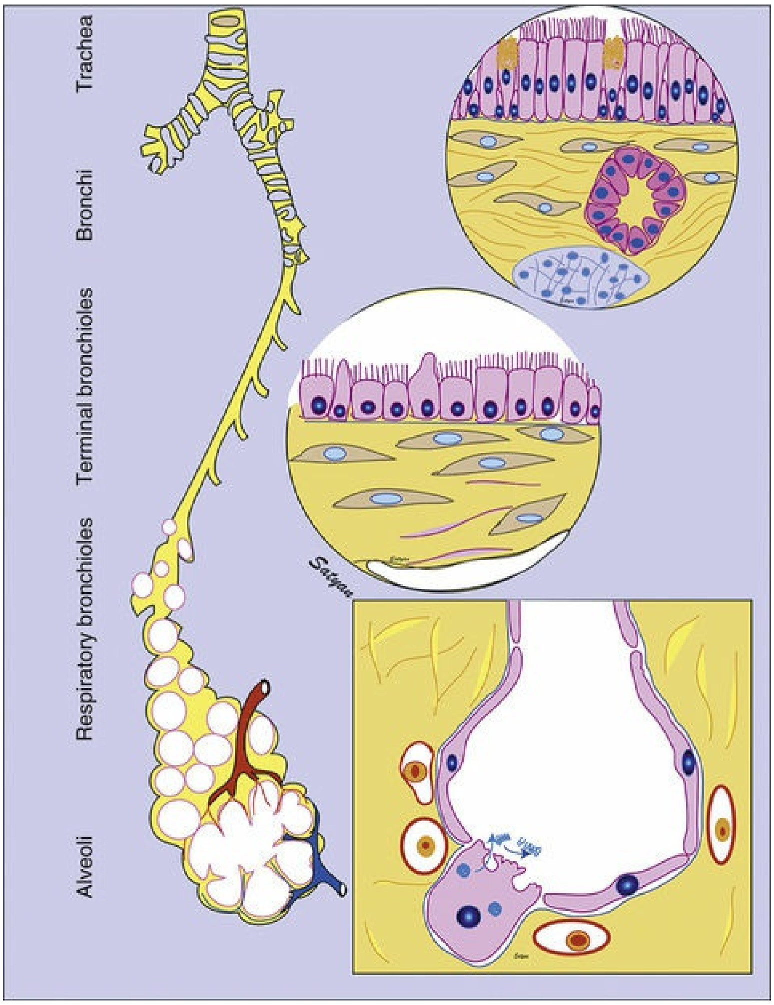

FIG. 44.5 Respiratory tract epithelia. There is a progression from pseudostratified columnar epithelium with ciliated, goblet, and basal cells in the large conducting airways (top circle) to a more cuboidal ciliated epithelium in the small conducting airways with nonciliated Clara cells (middle circle). In the alveolar epithelium, flattened type I pneumocytes and cuboidal type II pneumocytes are present and are associated with an extensive capillary network (box). (Copyright Satyan Lakshminrusimha.)

Within the wall of the bronchiole, the muscular layer becomes more prominent and submucosal glands and cartilage are absent. The bronchiole segment ends as a terminal bronchiole, which marks the terminus of the conducting portion of the airway. The terminal bronchiole branches into two generations of respiratory bronchioles, which through further divisions give rise to additional respiratory bronchioles that have more alveoli in their walls, so-called second- and third-order respiratory bronchioles. By definition, respiratory bronchioles are alveolated, and they branch into two to three generations of alveolar ducts. The alveolar ducts are defined as those channels from which a series of alveoli open and are histologically characterized by having small clublike ends that contain muscle sphincters and elastic fibers. The ducts open into a final generation of alveolus-lined spaces, the multiloculated cup-shaped alveolar sacs (Fig. 44.6).

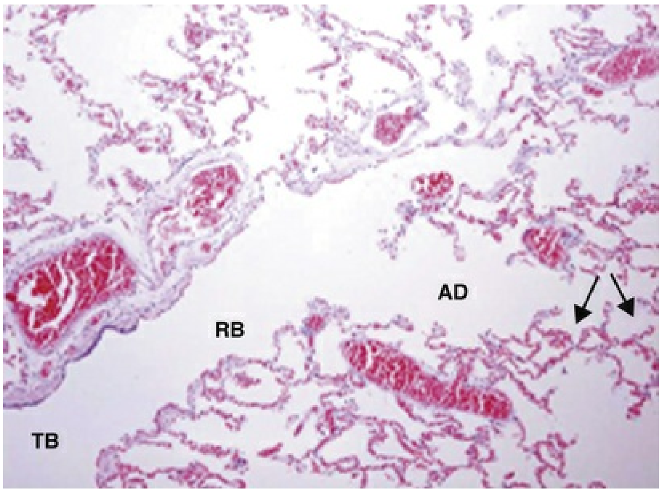

FIG. 44.6 Distal conducting airway with transition to respiratory airway. *AD,* alveolar duct; *RB,* respiratory bronchiole; *TB,* terminal bronchiole. Individual alveoli are indicated by *arrows.* (Hematoxylin-eosin stain; ×40.)

Definitions of Special Lung Unit and Alveolar Formation

Each bronchopulmonary segment is further compartmentalized into smaller units termed *pulmonary lobules.* Each pulmonary lobule is supplied by a bronchiole that divides into a cluster of three to five terminal bronchioles and their associated respiratory tissue situated at the end of a bronchial pathway. The pulmonary lobule is roughly 1 to 2 cm in diameter and pyramidal in shape. It is bound by delicate connective tissue septa in which small proximal branches of pulmonary veins travel. The portion of the pulmonary lobule distal to the terminal bronchioles and consisting of several respiratory bronchioles, alveolar ducts, and ultimately alveoli is

termed the *pulmonary acinus*. The acinus, which is approximately spherical in shape and has a diameter of about 7 mm and a length of 0.5 to 1 cm, is the gas exchange portion of the lung.

At the alveolar level, many changes occur in the postnatal period. Although there is disparity concerning the time alveolarization is completed, evidence links the postnatal development of alveoli with elastic tissue fiber deposition.[18] At birth, primitive alveoli called *saccules* are evident, but approximately 50 million alveoli are already formed.[19] The number of alveoli in a normal adult can vary from 300 to 500 million, and they have a diameter of 150 to 200 μm. The early work by Dunnell[20] suggesting that new alveolar formation ceased at about age 8 years has been challenged by Thurlbeck,[21] who has shown that alveolarization appears to be nearly complete at about age 2 years. Lung volume correlates with body size, but alveolar surface area correlates with metabolic activity; thus alveoli become more complex in shape during maturation and as increasing O_2 is required.

Alveolar-Capillary Unit

The alveolar-capillary unit is highly specialized to maximize diffusion between the blood and air gases (Fig. 44.7). The alveolar-capillary unit is composed of three major constituents: (1) the epithelial lining of the alveolus; (2) capillary endothelial cells; and (3) a mixture of cellular and extracellular interstitial components.[22] This alveolar-capillary bed is the most extensive in the body and is contained within the epithelium-lined walls of adjacent alveoli forming a gridlike network. The internal surface area of the adult lung is 70 to 80 m^2, of which 90% covers the pulmonary capillaries; thus the air-blood surface available for gas exchange is 60 to 70 m^2.[22] The endothelial cells, which constitute about 30% of the total lung cells, contain few intracellular organelles that are clustered together within the cytoplasm allowing the cell to maximize its surface area. A number of adenine nucleotides, vasoactive amines, prostaglandins, vasoactive peptides, and lipoproteins can be metabolized and taken up within the numerous pinocytotic vesicles characteristic of pulmonary endothelial cells.

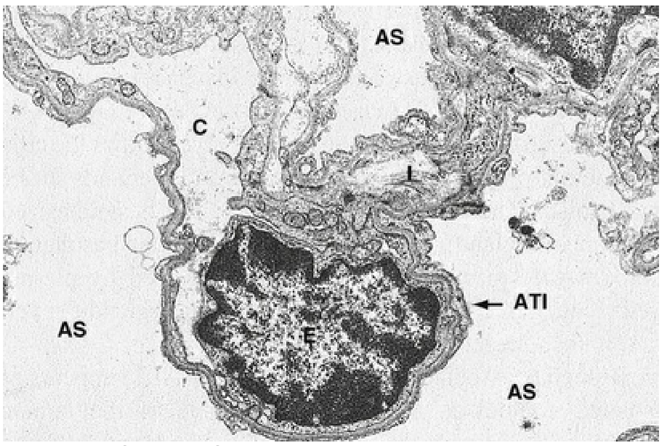

FIG. 44.7 Both surfaces of the alveolar wall that separates the alveolar spaces *(AS)* are covered by thin extensions of alveolar type I *(ATI)* epithelial cells. The capillary *(C)* is lined by endothelium *(E).* The epithelium and endothelium rest on a fused basement membrane on the

thin portion of the alveolar wall and are separated by an interstitial space *(I)* in the thick portion of the alveolar wall (×5500).

In addition to gas exchange, endothelial cells synthesize and secrete various locally acting substances such as nitric oxide, endothelins, prostacyclin, tissue plasminogen activator, and thrombomodulin. Other functions include liquid and solid exchange and enzyme activity within the walls of the caveolae. At the ultrastructural level the blood-air barrier consists of a 0.1- to 0.2-μm thick septum composed of a capillary endothelial cell and the type I pneumocyte with their intervening fused basal laminae. Within thicker portions of the alveolar wall, the alveolar epithelium and capillary endothelium are separated by the interstitial space.

The connective tissue space, or interstitium of the lung at the alveolar level, does not have lymphatics, but it can accumulate fluid that can be absorbed into the lymphatic system, which usually ends at the respiratory bronchiolar level. The interstitial cell population includes resident and migratory cell populations. Normally, the interstitium contains macrophages, pericytes, myofibroblasts, mast cells, infrequent lymphocytes, and a few cells that are best termed *undifferentiated, mesenchymal,* or *pluripotent* because in disease they can differentiate into various cell types including fibroblasts, smooth muscle cells, and others. Greater than 25% of the interstitial cells cannot be identified definitively with the electron microscope, so it is understandable why most of the cells cannot be identified by light microscopy without special cell marker stains.

Two epithelial cell types line the alveoli. Type I cells have thin cytoplasmic extensions and a large surface area covering approximately 90% of the total alveolar surface (Fig. 44.8). Numerically, they form only about 40% of the epithelial cells, whereas the type II cell, which is cuboidal, constitutes 60% of the total number of epithelial cells but contributes less than 10% of the total alveolar surface area. Type I cells are exquisitely well adapted to allow for the rapid exchange of gases, and their micropinocytotic system likely plays a major role in the transport of solutes, such as albumin and immunoglobulin, in small quantities. They can be induced to ingest some particulates and can increase their number of pinocytotic vesicles, but they are not active in surfactant uptake.

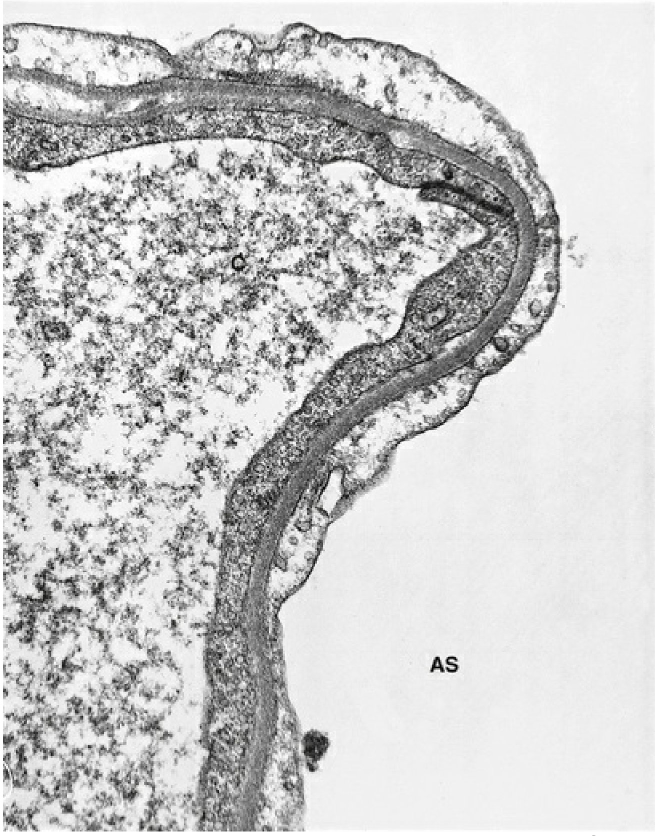

FIG. 44.8 Electron micrograph showing the thin side of the air-blood barrier. The thin cytoplasmic extension of the type I epithelium contains only a few vesicles and shares a fused basement membrane with the endothelium, which contains many caveolae (×18,000). *AS*, alveolar space; *C*, capillary.

The type II cell is the regenerative cell of the alveolar epithelium, serving as the stem cell following injury. It can repopulate the alveolar surface in about 5 days. It is cuboidal in shape and only numbers about one per alveolus. Ultrastructurally the type II cell has characteristic surface microvilli and cytoplasmic multilamellar inclusions, which are the intracellular cytoplasmic storage forms of pulmonary surfactant (Fig. 44.9). The inclusions evolve from multivesicular bodies or lysosomal granules, which progressively acquire the characteristic lamellae through fusion and condensation. In addition to its roles in the synthesis, secretion, and reuptake of surfactant, the type II cell synthesizes arachidonic acid metabolites, synthesizes and secretes connective tissue components of the basement membrane including fibronectin, synthesizes and secretes components of the complement system, expresses class II proteins of the major histocompatibility complex among others, and has been found to be a critical source of many different growth factors during injury and repair.[23]

FIG. 44.9 Cytoplasm of the alveolar type II cell has abundant lamellar inclusion bodies and surface membrane microvilli (×7500).

Considerable data demonstrate clearly that there are several populations of macrophages: intraalveolar, septal (interstitial), pulmonary intravascular, and airway. Within the alveolar spaces, alveolar macrophages are abundant and form an important arm of the defense mechanism of the lung (Figs. 44.10 and 44.11). They number approximately 23×10^9 in the lung (10% of the total cells of the alveolar compartment), and 50 to 100 are estimated per alveolus. They derive from three sources: bone marrow via blood monocyte, the interstitial macrophage pool, and proliferation of macrophages in the alveolar space. They are actively phagocytic and scavenge the surface of the alveoli for respired particulates (macrophages as so-called "dust cells"). Although seen free-floating in alveolar spaces in light microscopic preparations, the alveolar macrophage crawls along the surface of epithelium, adhering with its filopodia. The macrophage has remarkable metabolic activities, has known immune functions, and is involved in lung injury and repair phenomena. Alveolar macrophages also play a role in surfactant uptake, removal, or catabolism. More than 100 macrophage-synthesized mediators have been identified, including many proinflammatory cytokines, and numerous ligands have been demonstrated. In normal bronchoalveolar lavage fluid, 90% of the cells are alveolar macrophages and 1% to 5% are lymphocytes (T-cell lymphocytes constituting 60% to 70% and B cells 5% to 10%).

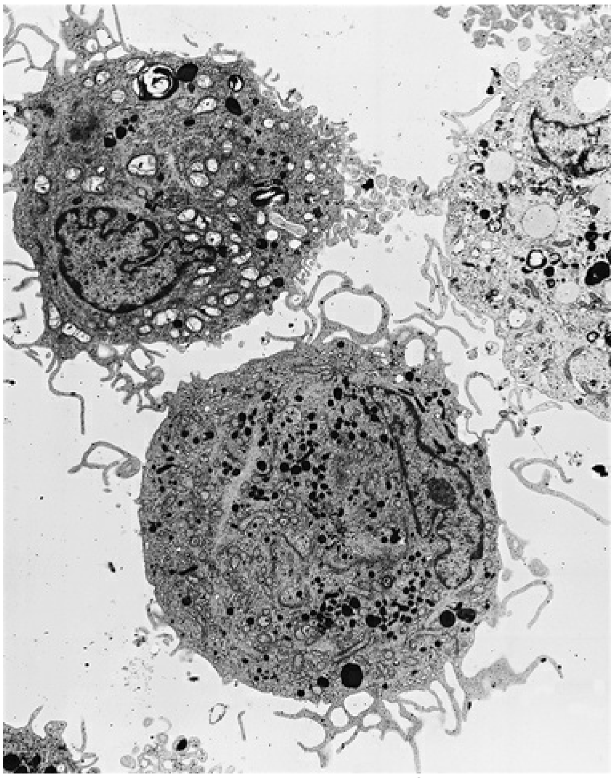

FIG. 44.10 Alveolar macrophages recovered from bronchoalveolar lavage fluid contain abundant lysosomes and other cytoplasmic contents, including lipid droplets and surfactant remnants (×5300).

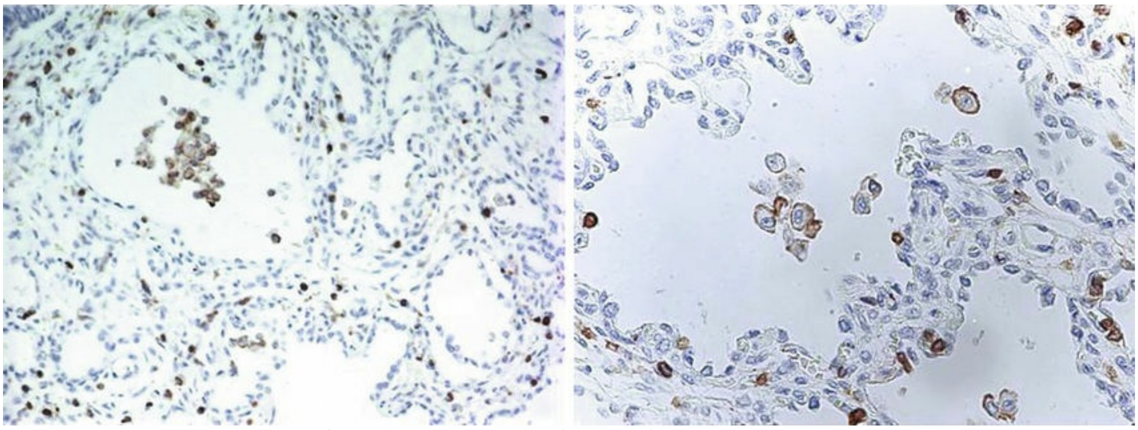

FIG. 44.11 Sections obtained from infants who died with bronchopulmonary dysplasia. Pulmonary macrophages present within air spaces were immunostained (brown stain) with anti-CD45, a general leukocyte marker. Leukocytes are also identified within the alveolar walls and capillaries. (hematoxylin counterstain; ×200 left, ×400 right.) (Original lung section courtesy Dr. Gloria Pryhuber.)

Lung Circulation

Pulmonary Vascular System

The pulmonary circulation is furnished by the pulmonary and bronchial vascular systems.[24,25] During gestation, branches of the pulmonary arterial system are thick walled and contain a medial layer of smooth muscle. At birth, the pulmonary artery and aorta are comparable in medial thickness and configuration. Elastic fibers tend to be long, uniform, unbranched, and parallel with one another. Following birth the pulmonary vasculature undergoes extensive remodeling and by 2 years of age shows a media composed of short, branched, and loosely arranged elastic fibers. When fully matured the pulmonary artery and its thickness are only about 60% that of the aorta. Only a few muscular arteries are seen accompanying terminal bronchioles at birth. Following birth, when pulmonary arterial pressures fall to normal levels, the muscle fibers diminish. Initially new vessels without muscle are formed, along with new respiratory units during lung growth. Smooth muscle extends peripherally into small arteries slowly, reaching arterioles at the respiratory bronchiolar level at 4 months, alveolar duct level at 3 years, and some alveoli at age 10 years.[26]

The criteria for recognizing various types of pulmonary vessels were put forth by Brenner in 1935.[27] The pulmonary arteries, which exceed 1000 μm in external diameter, are called elastic pulmonary arteries and traverse with the cartilaginous airways. They extend from the hilum to nearly halfway in the bronchial tree of the newborn, a pattern completed by week 16 of gestation and retained into adulthood. Pulmonary arteries measure between 100 and 1000 μm in diameter and have a distinct muscular media and internal and external limiting elastic membranes. The muscular arteries of the lung have thinner media than their counterparts in the systemic circulation. Muscular pulmonary arteries branch with the bronchial tree and lie close to bronchi and bronchioles (Fig. 44.12). Pulmonary arterioles are vessels that measure 100 μm in diameter and have only an endothelial lining and a single elastic lamina with little, if any, muscular media. These vessels usually are seen at the level of the alveolar ducts and in certain sites within the alveolar walls. Pulmonary capillaries are nonfenestrated, whereas bronchial capillaries are fenestrated. The appearance of pulmonary venules is identical to that of pulmonary arterioles, and serial sections are required to differentiate the two. In contrast with the pulmonary arteries, the larger branches of pulmonary veins do not course with the bronchial tree; instead, they are seen within the interlobular septa. The media of larger veins is composed of smooth muscle fibers, collagen, and elastin. Unlike their arterial counterpart, these veins show no clear internal and external elastic lamina (Fig. 44.13).

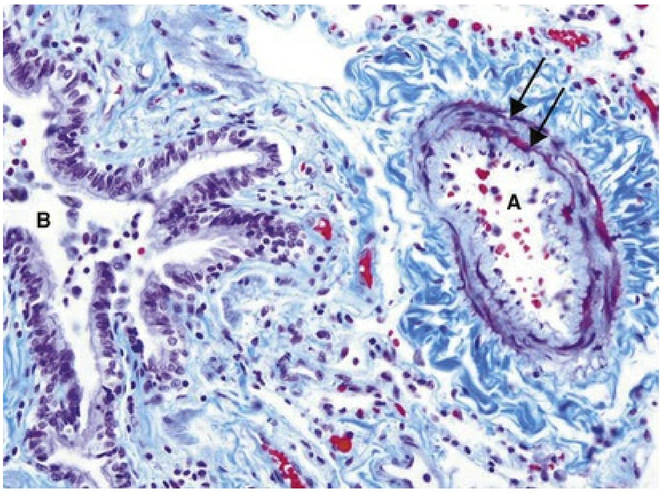

FIG. 44.12 Small muscular pulmonary artery *(A)* traveling with a bronchiole *(B).* Two layers of smooth muscle cells are present in the vascular media *(arrows).* (Gomori trichrome; ×200.)

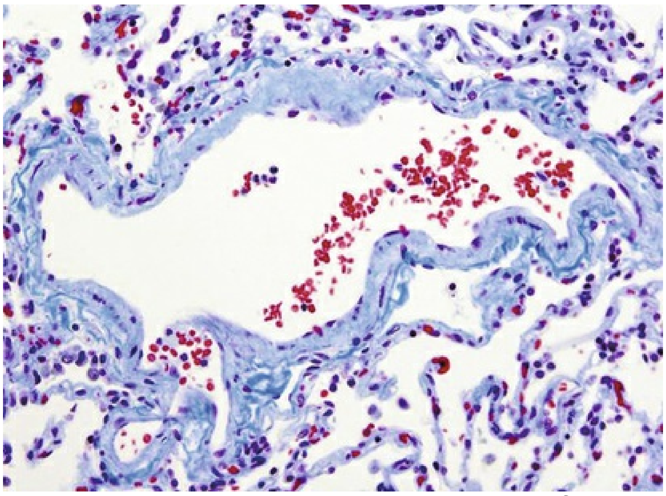

FIG. 44.13 Pulmonary vein. The media is composed of loose, pale, blue-staining collage fibers with scarce smooth muscle present. (Gomori tricrome, ×200.)

Bronchial Vascular System

Whereas the pulmonary circulation returns all venous blood to the lung and serves some nutritive function to peripheral capillaries, the bronchial circulation is the primary blood source for the lung. Although two major bronchial arteries for each lung is a common pattern, this is present less than 40% of the time. There usually are two bronchial arteries in the left lung and one in the right lung. Although variable, the left bronchial arteries usually arise from the upper portion of the descending aorta. The right bronchial artery arises from the descending aorta, one of the right intercostal branches, or subclavian or internal thoracic arteries. The bronchial arteries traverse along the dorsal portion of each bronchus. They lose their distinctness along the respiratory bronchioles and drain with the alveolar capillaries into the

peribronchiolar venous network. They form a capillary plexus in the bronchi that supplies the submucosa and muscle. The capillary plexus communicates with branches of the pulmonary artery that empty into pulmonary veins. Other bronchial arteries supply the interlobular tissue and the pleura. They drain into the bronchial veins. The diameter of the bronchial artery is much smaller than that of the accompanying pulmonary artery. It has an internal elastic lamina and media but no external elastic lamina.

Pulmonary Lymphatics and Bronchus-Associated Lymphoid Tissue

Pulmonary lymphatics[24] invariably have less elastic tissue in their walls than either arteries or veins.[24,25] They are lined by endothelium, and valves are present especially near and in the visceral pleura. There are two lymphatic systems in the human lung: a superficial network in the pleura and a deep network around the bronchi and pulmonary arteries and veins and in the connective tissue septa between the pulmonary lobules. The two separate systems have anastomoses, in both the pleura and near the hilum. Lymphatics can be demonstrated to the level of the septal walls but are not found at the alveolar level. Lymph flow from both lower lobes drains into the infratracheal lymph nodes. The remaining right and left lung lobes drain into the tracheobronchial lymph nodes on each side of the trachea, respectively. Lymph from the right tracheobronchial nodes drains into the right bronchomediastinal trunk, whereas the left tracheobronchial nodes drain into the thoracic duct.

Understanding the lymphatic drainage of the pleura is of clinical value. All lymph from the visceral pleura eventually reaches parabronchial and hilar lymph nodes by flowing on the surface or in lymphatic trunks that course through the lung. Lymphatic vessels in the parietal pleura are in communication with the pleural space via 2- to 6-mm stomas found on the mediastinal pleura or the intercostal surfaces of the lower thorax.[28] The parasternal nodes in the second and third interspaces receive lymph from a significant portion of the parietal pleura, so biopsy of these nodes may reveal an etiology of the pleural effusion. The portion of lymph that drains caudally from the lower parietal pleural region into retroperitoneal nodes can explain metastases of tumor to adrenals and kidneys.

Bronchus-associated lymphoid tissue (BALT) appears as isolated nodules in the connective tissue of the lamina propria of the bronchial tree and produces primarily IgG and secretory IgA.[29] Collections of BALT cells tend to occur at airway bifurcations and are covered by a special epithelium that can pinocytose and transport solutes and particulate antigens. BALT is sparse at birth but starts accumulating thereafter. It is prominent in lungs of children and in diseased lungs of patients with bronchiectasis. Although more than 50% of the cells are B lymphocytes, T lymphocytes are also found (18%), along with follicular dendritic cells. Sometimes these nodules bulge into the bronchial lumen.[29] Additional lymphoid tissue in the lung is a rich supply of lymph nodes within the lung, at the carina, and along the trachea.

Diaphragm

Although the diaphragm is the principal muscle of respiration, it is not essential for breathing in the awake state. It becomes essential during deep anesthesia because other muscles of respiration become inactive. The diaphragm is a musculotendinous sheet that is the main source of inspiratory muscle force.[24,28] Anatomically it separates the thoracic from the abdominal cavity. It has two distinct muscular components: the sternocostal portion and the crural. These two portions have distinct embryologic origins and have separate segmental innervations and varying muscle fiber composition. There are changes in fiber composition following birth. The muscle fibers vary morphologically, physiologically, and cytochemically. The diaphragm has three openings near its central portion for the aorta, inferior vena cava, and esophagus. The vagus nerve passes through the esophageal hiatus, whereas the azygos vein and thoracic duct pass through the aortic hiatus. There are small paravertebral perforations for splanchnic nerves. Because of the way the fibers originate from the bones and traverse to the central tendon, triangular areas may result in spaces or clefts in the diaphragm. Anteriorly these are called Morgagni foramina, and posteriorly they are known as the *foramina of Bochdalek.* Both are potential sites for hernias. The phrenic nerve innervates the diaphragm.

During contraction in adults, the dome of the diaphragm descends and the lower ribs elevate. In infants, because of their compliant rib cage, descent opposes elevation of the lower ribs and results in the subcostal retractions.[28] Other muscles of respiration include the intercostals, the majority of which are arranged to enhance inspiration by elevating the lower ribs, and the abdominal muscles, which are powerful muscles of expiration but do not participate in expiration during quiet breathing. Scalenes act to elevate the first two ribs and are active even during quiet breathing. Although the sternocleidomastoid muscles usually are not active in quiet breathing, when inspiratory efforts are marked, they become the most important accessory muscles of inspiration. This is well seen in infants with respiratory distress who elevate the upper portion of their sterna.

Summary

The respiratory portion of the lung is a complex organ with more than 40 cell types. It undergoes remodeling over the first few years of life. Altered structure, whether due to congenital abnormalities or injury and repair, is a critical determinant of survival and quality of life. Understanding the structure of the lung is critical to the management and treatment of lung disease in critically ill children.

CHAPTER 45

Physiology of the Respiratory System

Mark J. Heulitt, Katherine C. Clement

PEARLS

- During childhood, the most important chest diseases have obstructive pictures that are best measured using interrupter and oscillation techniques.
- Wheezing is a sound heard when there is flow limitation in a compliant tube. It is a sign of expiratory flow limitation. The wheezing is caused by "flutter" of the walls at the site of flow limitation secondary to the conservation of energy in the system.
- The respiratory system is not a linear system; resistance and compliance are not constants. They are dependent on volume, volume history, and flow.
- The equation of motion changes when a spontaneously breathing patient is placed on positive pressure mechanical ventilator support. The pressure applied to the airway (P_{APP}) equals the sum of pressure generated by the patient's muscles (P_{mus}) plus the ventilator pressure (P_{vent}). Thus:

$$P_{mus} + P_{vent} = \frac{1}{C}V + R\dot{V}$$

Physiology of the Respiratory System

Because of the increasing emphasis on molecular biology today, many physicians currently in training have received limited exposure to physiologic principles that form the basis of clinical medicine. However, a resurgence of interest in translational research has occurred recently with a reemphasis on molecular research and applied animal physiology before these principles are used in clinical research.[1] In a recent editorial in the *European Journal of Physiology*, Rossier[2] stated that research is refocusing itself to make a change from the past, where its mantra was "from function to the gene," to the future, where the focus must be on the "gene to

function." That "structure determines function" relates to that first lecture in physiology when it was discussed that changes in the shape of a protein, cell, or organ will usually result in a change of function of that structure. This is never so true as in a discussion of the physiology of positive pressure mechanical ventilation in pediatric patients. The focus of this chapter is to expose the reader to the important basic principles of respiratory physiology and to serve as a primer to other chapters in this book that use these principles.

The main function of the lungs is (rapid) gas exchange. This process is accomplished by a well-coordinated interaction of the lungs with the central nervous system, the diaphragm and chest wall musculature, and the circulatory system.

Gas exchange occurs in the alveolus, where the thin laminar blood flow and inspired air are separated only by a thin tissue layer. Gas exchange takes 0.25 seconds or one-third of the total transit time of a red cell. The entire blood volume of the body passes through the lungs each minute in the resting state, approximately 5 L/min. The total surface area of the lung is about 80 meters square, equivalent to the size of a tennis court. The primary function of the lungs is to supply oxygen (O_2) and to remove carbon dioxide (CO_2) from the tissues of the body. For the lungs to do this, two interrelated processes must occur: ventilation, which is the movement of air between the outside body and the alveoli, and gas exchange, which is the transfer of O_2 and CO_2 between the alveolar gas and the mixed venous blood entering the lungs.

Approximately 10% of the lung is occupied by solid tissue, whereas the remainder is filled with air and blood. However, it should be noted that changes occur with development. A gram of lung from an infant probably represents more airway tissue and less parenchymal (alveolar and interstitial) tissue than the same amount of lung from an adult. Supporting structures of the lung must be delicate enough to allow gas exchange yet strong enough to maintain the architectural integrity needed to sustain alveolar structure. The functional structure of the lung can be divided into (1) the conducting airways (dead air space) and (2) the gas exchange portions. The two plumbing systems are airways for ventilation and the circulatory system for perfusion. Both systems are under low pressure.

Conducting Airways

The diameter of the lower airways is maintained by a balance of forces. Sympathetic impulses relax and parasympathetic impulses constrict the muscles. Airway dilatation may occur as a result of sympathomimetic agents (eg, epinephrine or adrenaline). Narrowing forces are bronchial smooth-muscle contraction, mediated by efferent autonomic nerve control. Constriction also can occur as a result of irritants (eg, dust, smoke, or cold); hyperventilation; and vasoactive agents (eg, acetylcholine, histamine, or bradykinin).

Additional narrowing occurs during forced expiration, when there is dynamic airway compression caused by pleural and peribronchial pressures. This narrowing is counteracted by intraluminal pressure and tethering action of the surrounding lung. The luminal diameter of a branch is related to the number of alveoli at the end of that branch (axial and lateral pathways). Because the longer airways with more branches and more alveoli usually have a wider lumen that allows greater airflow, newly inspired air reaches all of the alveoli throughout both lungs at the same time

and in approximately the same amount, that is, an even distribution of inspired air throughout all lobes in a given period of time. There are approximately 23 airway divisions to the level of the alveoli. The divisions include main bronchi, lobar bronchi, segmental bronchi (to designated bronchopulmonary segments), and so on to the smallest bronchioles, which do not have alveoli and are lined completely by bronchial epithelium. These are the terminal bronchioles. Although the base airway diameter decreases with branching, the overall or total cross-sectional diameter increases tremendously so that peripheral airway resistance decreases.

Model of the Respiratory System

The respiratory system can be represented by a collection of physical components interacting with one another and with their environment. Although in vivo analysis demonstrates that the lungs do not function as a single compartment, analyzing the respiratory system in a linear model simplifies the presentation.

A single balloon on a pipe is the simplest model, although this model has its deficiencies because the airway is more complex than a simple pipe. Also, it now appears that the alveolus is not simply a single balloon or group of balloons similar to a cluster of grapes. It is now known that the alveoli are not physically independent structures but are actually interconnected.[3] An excellent review of the structure of the alveoli and the role of surfactant is offered by Gatto et al.[4] However, to lay the groundwork for our understanding of respiratory mechanics, we consider the simple model of a balloon on a pipe.

The relationship at any moment (t) between the pressure applied at the opening of the model (P[t]) and the volume in the model (V[t]) during emptying of this balloon can be described as a first-order model:

$$P(t) = E \cdot V(t) + R \cdot \dot{V}$$

where *E* is the elastance of the balloon, *R* is the resistance of the pipe, and $\dot{V}$ is the flow through the opening. Using regression analysis, E and R can be calculated from P(t), V(t), and V(t).

The values of R and E, as applied to the respiratory system, reflect the resistance of the airways and the elastance of the respiratory system, whereas V(t) is the volume increase from functional residual capacity (FRC) when the mouth pressure is zero.

The three important components of this linear model are the time constant (τ), compliance (C) or elastance (E), and resistance (R). The relationship of these is given by the equations:

$$\tau = C \times R \text{ or } \tau = R/E$$

Each of these components will be discussed separately.

Elastic Properties of the Respiratory System

The respiratory system is composed of a collection of elastic structures. The response to a force applied to the elastic structure of the respiratory system is to resist

deformation by producing an opposing force, known as *elastic recoil,* to return the structure to its relaxed state.[5] In the respiratory system this opposing force produces a pressure known as the *elastic recoil pressure* (P_{EL}). The force required to stretch an elastic structure depends on the volume at which the outward recoil of the chest wall balances the inward recoil, known as the *elastic equilibrium volume.* The pressure of the elastic recoil or P_{EL} divided by the lung volume (V) gives a measure of the elastic properties of respiratory system and is called *elastance* (E):

$$E = P_{EL}/V$$

When lung volume is plotted on the ordinate and P_{EL} is plotted on the abscissa, the slope of the static pressure-volume curve is equivalent to the reciprocal of elastance, called *compliance*.

For ventilation of the lungs to occur, the forces necessary to overcome the elastic, flow-resistive, and inertial properties of the lungs and the chest wall must be produced to create motion of the respiratory system. In normal circumstances, respiratory muscles produce these forces.

Overcoming forces to move gas into the airway can be exemplified by moving a block of wood over a surface. The movement of the block is determined by the friction between the block of wood and the surface and how fast the wood is moving. It is irrelevant what the block's position is. Similarly, the pressure required to produce a flow of gas between the atmosphere and the alveoli must overcome the frictional resistance of the airways. This pressure is proportional to the rate at which volume is changing or flow *($\dot{V}$)* as follows:

$$P_{mouth} - P_{alv} = P_{fr}\alpha\dot{V} \text{ or } P_{ao} - P_A = P_{fr}\alpha\dot{V}$$

where P_{ao} is pressure at the airway opening (usually atmospheric pressure), P_A is the alveolar pressure, and P_{fr} is the pressure required to overcome frictional resistance. The pressure required to produce a unit of flow is known as *flow resistance* (R):

$$R = P_{fr}/\dot{V}$$

If the respiratory system is modeled as a single compartment with a single constant elastance (E) and a single constant resistance (R), then the equation of motion describes the balance of forces acting on the system as follows:

$$P = EV + R\dot{V} + I\dot{V}$$

The inertia *(I)* is usually negligible and therefore ignored. Of the pressure produced during normal tidal respiration, most is required to overcome the elastic forces and a minimal amount is required to overcome the flow-resistant forces.

Traditionally it was thought that little energy was dissipated by the tissues of the respiratory system and that the majority of the force developed during breathing

was required to move gas through the airways. The lung parenchyma is a complex system consisting of alveolar walls composed of collagen, elastin, and proteoglycan macromolecules; an air-liquid interface of surfactant; and cells that have the capacity to act in a contractile fashion, called *interstitial cells.* The viscoelastic behavior of the pulmonary parenchyma could potentially explain this behavior. In addition, this action is difficult to study because it is unclear where the boundary of the airways end and parenchyma begins. Airway smooth muscle exists in the terminal bronchioles and alveolar ducts, and the behavior of these structures may well influence parenchymal mechanics.

The energy expended moving the tissue is called the *tissue viscance* or resistance, although it is a non-Newtonian resistance. In other words, the viscosity depends on the force applied. When measured during inspiration, the tissue resistance increases with increasing lung volume, whereas airway resistance falls. Tissue resistance comprises approximately 65% of respiratory system resistance at FRC in mechanically ventilated animals and increases as much as 95% at higher lung volumes.[6] The contribution of tissue resistance to respiratory system resistance in humans under the same circumstances is unknown.

Resistance is expressed as changes in pressure divided by changes in flow:

$$R = \Delta P / \Delta \dot{V}$$

The other part of elastic recoil depends on the surface tension at the alveolar gas-liquid interface (surface forces). Surface tension is produced by the interface between air in the alveolus and the thin film of liquid that covers the alveolar surface. Surface tension in the alveolus is created by interacting water molecules that direct a force inward and could cause the alveoli to collapse. This action is described by La Place's equation where the pressure inside a bubble exceeds the pressure outside the bubble by twice the surface tension, divided by the radius. In other words, the smaller a bubble, the more the pressure inside exceeds the pressure on the outside. La Place's equation is defined as:

$$P = 2T/r$$

where P is the internal pressure, T is the tension in the wall of the structure, and r is the radius. When comparing two different alveoli with the same surface tension, the smaller the radius, the greater the pressure created by a given surface tension. Air will flow from high pressure (small alveoli) to lower pressure (larger alveoli). Thus smaller alveoli are more likely to collapse. The surface tension of the alveoli is affected by a substance produced in the alveoli called *surfactant.* Surfactant contains a mixture of lipids and proteins, is manufactured by alveolar type II cells, and exists as a monolayer on top of the alveolar subphase. Three surfactant-associated protein groups have been identified.[7] Surfactant acts to lower surface tension at the alveolar air-liquid interface and thereby decreases elastic recoil of the lungs.[8] Another action of surfactant is to reduce the development of pulmonary edema by diminishing one component of the pressure gradient driving transudation. In the lung there is a gradient between pulmonary capillary pressure and the interstitial pressure that

surrounds the capillary. In most of the lung, the pulmonary capillary pressure is greater than the interstitial pressure; thus pulmonary edema would develop if not checked by the oncotic pressure of the plasma proteins. By reducing surface tension, the surfactant reduces the interstitial pressure and transcapillary gradient, but if there is a deficiency of surfactant and thus a rise in surface tension, pulmonary edema may develop.[9] Also, surfactant has been described as an antiwetting agent that helps to keep the lungs dry.[10] Currently there is agreement on the fact that surfactant plays an essential role in alveolar mechanics, but its mechanism is debated. The aforementioned description outlines the classic discussion on the role of surfactant, but diverse opinions exist on its true role. Scapelli[11] has described the role of the surfactant foam bubbles within the alveoli as “inner tubes.” In contrast, Hills proposes that surfactant coats the alveolar walls as a “biologic wax.”[12,13] The clinical implications of a deficiency of surfactant has been described in a famous editorial by Lachman entitled “Open Up the Lung and Keep the Lung Open.”[14]

Compliance and Elastance

Compliance is how much a compartment will expand if the pressure in that compartment is changed. An elastic balloon has a high compliance because a small pressure increase inside the balloon will greatly expand the balloon. A rigid tube has a low compliance because a small pressure increase inside the rigid tube will not result in a significant increase in the volume of the rigid tube. Two major forces contribute to lung compliance: tissue elastic forces and surface tension forces. The compliance (C) is determined by the change in elastic recoil pressure (ΔP) produced by a change in volume (ΔV):

$$C = \Delta V / \Delta P$$

The compliance of the lungs (C_L), chest wall (C_{CW}), and respiratory system (C_{RS}) can be determined by measuring the change in distending pressure and the associated change in volume. The distending pressure represents the pressure change across the structure, where P_{ao}, P_{pl}, and P_{bs} represent the pressure measured at the airway opening, pleural pressure, and pressure at the body surface (atmospheric pressure), respectively:

$$C_L = \Delta V / \Delta (P_{ao} - P_{pl})$$
$$C_{CW} = \Delta V / \Delta (P_{pl} - P_{bs})$$
$$C_{RS} = \Delta V / \Delta (P_{ao} - P_{bs})$$

Lung volume and volume-pressure relationships (eg, compliance) reflect parenchymal (air space) development, whereas airflow and pressure-flow relationships (resistance and conductance) predominantly reflect airway development. The lungs become stiffer (compliance decreases) at higher lung volumes.

Pulmonary compliance changes with growth and maturation depending on the number of expanded air spaces, size and geometry of the air spaces, characteristics

of the surface lining layer, and properties of the lung parenchyma. This shift is represented by changes in the shape of the volume-pressure curve. When these curves are corrected by expressing the volumes as a percentage of the maximal observed lung volume, they are more curved in infants than in older children (Fig. 45.1).[15] It is important to note that there may be boundaries for dynamic changes in alveolar size and shape during ventilation because of the tensile forces of the connective tissue and surface tension supporting the alveoli and alveolar ducts.

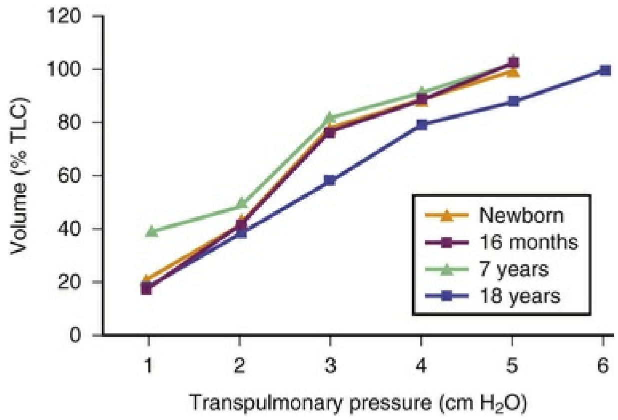

FIG. 45.1 Deflation volume-pressure curves of the lung at different ages (obtained from studies on excised lungs).[9] With increasing age up to young adulthood, the curves become straighter and, at a given lung volume, elastic recoil pressure is greater. The curve from elderly individuals resembles that from a 7-year-old respiratory system. *TLC,* total lung capacity.

The developmental change in shape of the volume pressure curve represents the maturation of alveoli and hence differences in the elastin-collagen ratio with age.[15] The lung volume (as a percent of maximal lung volume) at which airway closure occurs is higher in children younger than 7 years[16] and is closer to their functional residual volume. Pressure-volume relationships are also more curvilinear in infants.[17] Chest wall compliance is 50% greater in infants.

Elastance is defined as the change in distending pressure divided by the associated change in volume:

$$E = \Delta P/\Delta V$$

Elastance is therefore the reciprocal of compliance; thus stiff lungs have a high elastance.

Elastic Recoil of the Respiratory System

In the intact thorax, the inward recoil of the lungs is opposed by the outward recoil of the chest wall (when it is below its resting volume). Both the lungs and chest wall recoil inward when chest volume exceeds its resting volume. These recoil forces act as though arranged in series.

The pressure required to balance the elastic recoil of the lungs, chest wall, and respiratory system (elastic recoil pressure) may be determined by having a subject

exhale in increments from total lung capacity (TLC) to residual volume. At each volume, the subject relaxes against a fixed obstruction with glottis open, and the pressure difference across the lung, chest wall, and entire respiratory system is recorded. Pressure volume curves are derived in this way for the respiratory system, and its components are shown in Fig. 45.2.[18] The static pressure-volume curves of the respiratory system, lung, and chest wall are different during inspiration and expiration. Thus lung volume at a given transpulmonary pressure is higher during deflation than during inflation. This phenomenon is called *hysteresis.* Hysteresis is the failure of a system to follow identical paths of response on application and withdrawal of a forcing agent, as occurs during inspiration and expiration. Hysteresis in the respiratory system depends on viscoelasticity, such as stress adaptation (ie, rate-dependent phenomenon), and on plasticity (ie, a rate-independent phenomenon). In the lungs, hysteresis is due primarily to surface properties and alveolar recruitment-derecruitment. In comparison, the chest wall hysteresis is related to the action of both muscles and ligaments because both skeletal muscles and elastic fibers exhibit hysteresis. Hysteresis is negligible when volume changes are minimal, such as during quiet breathing. This phenomenon is important because the area of the hysteresis loop represents energy lost from the system.

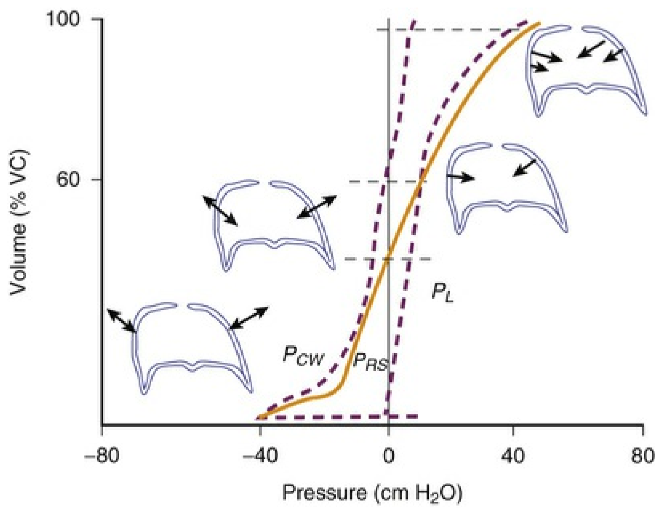

FIG. 45.2 Pressure-volume relationship of the lung *(P_L)*, chest wall *(P_{CW})*, and entire respiratory system *(P_{RS})*. *Large arrows* represent the elastic recoil of the lungs and the chest wall. (Modified from Agostoni E, Mead J. Statics of the respiratory system. In: Fenn WO, Rahn H, eds. Handbook of Physiology, Respiration, vol 1. Washington, DC: American Physiological Society; 1964:392.)

The resting volume of the respiratory system, the FRC, is the volume at which the elastic recoil of the lungs and the chest wall exactly balances each other. Above and below this equilibrium point, progressively increasing pressure is required to change the volume of the respiratory system. The total pressure required at each volume is the sum of the pressures required to overcome the elastic recoil of the lungs and chest wall.

Flow Resistance of the Respiratory System

The response of the lung to movement is governed by its response to the physical impedance of the respiratory system. The impedance can be categorized into (1) elastic resistance between the alveolar gas/liquid interface and tissue and (2) frictional resistance to gas flow. Under static conditions, pressure is required only to oppose the elastic recoil of the respiratory system. However, when the lungs and chest wall are in motion and movement of air into and out of the lungs occurs, pressure also must be provided to overcome the frictional or viscous forces. The ratio of this additional pressure (P) and the rate of air flow that it produces $(\dot{V})$ is defined as the resistance:

$$R = P/\dot{V}$$

In other words, the flow $(\dot{V})$ measured at the mouth depends on the driving pressure (ie, the pressure difference between alveoli [P_{alv}] and mouth [P_{mo}]) and the airway resistance (R_{aw}):

$$\dot{V} = (P_{mo} - P_{alv})/R_{aw}$$

If the mouth pressure is zero (ie, atmospheric pressure), the driving pressure is the alveolar pressure.

Airways resistance (R_{aw}) is the sum of the peripheral airways resistance (peripheral intrathoracic airways <2 mm diameter; R_{awp}), the central airways resistance (large intrathoracic airways >2 mm diameter; R_{awc}), and the extrathoracic airways resistance (especially glottis; R_{ext}). In healthy people, R_{ext} accounts for 50% of the total R_{aw} and R_{awp} for about 15%. R_{awp} and R_{awc} are influenced by lung volume. Higher lung volumes give higher P_{el} and therefore increase airway diameter. With increasing volumes during inspiration, the increased P_{el} is counteracted by P_{pl}, resulting in increased radial distending force. This distending force is the transmural pressure and is the difference between pressure in (P_{in}) and pressure outside (P_{out}) the airway.

At zero airflow the pressure inside the airways (P_{in}) equals atmospheric pressure and transmural pressure (P_{tm}) equals the elastic recoil pressure (P_{el}):

$$P_{in} = P_{mo}, P_{tm} = P_{el}$$

The total respiratory resistance (R_{rs}) consists of the resistance of the airways (R_{aw}), resistance of the lung (R_L), and resistance of the chest wall (R_{cw}):

$$R_{rs} = R_{cw} + R_L + R_{aw}$$

In older children, R_{cw} and R_L represent only 10% to 20% of R_{rs},[19] but in newborns, R_L could be higher.[20]

Airway diameter of the intrathoracic airways approximates to a sigmoidal relationship with P_{tm}. This relationship results in volume dependency of R_{aw}. At higher lung volumes R_{awp} decreases. The specific relation between R_{awp} (or its reciprocal conductance G_{aw} [$=1/R_{aw}$]) and volume is mirrored by the specific R_{aw} (sR_{aw}) and specific G_{aw} (sG_{aw}):

$$sR_{aw} = R_{aw}/V$$

The resistance of the airways (R_{aw}), lungs (airway and parenchyma) (R_L), chest wall (R_{cw}), and entire respiratory system (R_{RS}) can be calculated by measuring the rate of airflow and the associated trans-structural pressure by subtracting from the total pressure the amount required to overcome elastic recoil:

$$\begin{aligned}
R_{aw} &= (P_{ao} - P_{alv})/\dot{V} \\
R_L &= (P_{ao} - P_{pl})/\dot{V} \\
R_{cw} &= (P_{pl} - P_{bs})/\dot{V} \\
R_{RS} &= (P_{ao} - P_{bs})/\dot{V}
\end{aligned}$$

where P_{ao}, P_{alv}, P_{pl}, and P_{bs} represent the pressure at the airways opening, alveolar pressure, pleural pressure, and pressure at the body surface, respectively. The resistance of the lung parenchyma may be derived by subtracting airway from total lung resistance.

The relationship between the flow rate and the airway pressure gradient is nonlinear because of the relative contribution of the various components of the respiratory system to the total pressure required to overcome the viscous forces and its dependence on volume, volume history, and flow. The viscous forces increase disproportionately as the flow rate increases and as airway resistance increases. In contrast, the resistance of the chest wall and lung parenchyma remains constant over a wide range of flow rates.[21] During quiet breathing by mouth, airway resistance accounts for greater than 50% of the total respiratory system resistance.[22] However, as flow rate increases, the contribution of the airways to total resistance progressively increases.

Changing patterns of airflow result in the nonlinear flow-resistance characteristic of the airways. Subsequently, as the flow rate to the airway increases, airflow becomes progressively more turbulent. The more turbulent the flow, the greater the pressure required to overcome the viscous forces. Turbulence occurs at lower flow rates in the upper airway compared with the lower (intrathoracic) airways because of the tortuous geometry of the upper (extrathoracic) airway and the narrow glottic aperture. Therefore, the upper airway is responsible for most of the increase in airway resistance with an increase in flow rate. Studies have shown the resistance of the lower airways to be nearly constant up to flow rates of 2 L per second.[21] For patients who are breathing quietly by mouth, total airway resistance is divided

almost equally between the upper and lower airways. As their effort increases, flow rate increases, and the ratio of upper to lower airway resistance progressively increases as previously described.

Depending on whether laminar or turbulent flow predominates, resistance to airflow varies inversely with either the fourth or fifth power of airway radius.[23] Therefore major changes in airway resistance are caused by factors that affect airway diameter.[24] During spontaneous lung inflation, airway diameter increases as airway resistance decreases. This change is produced by two mechanisms. First, as lung volume increases, the increasing elastic recoil of the pulmonary parenchyma provides a tethering effect that dilates the intrapulmonary airways. Second, extrapulmonary and large intrapulmonary airways are surrounded by pleural pressure, which becomes increasingly negative during inspiration. This phenomenon leads to an increasing pressure gradient across the airway wall and therefore to an increasing diameter. The change in airway resistance with lung volume is curvilinear and is illustrated in Fig. 45.3.[24] When the reciprocal of airway resistance, airway conductance (G_{AW}), is plotted against lung volume, this relationship is nearly linear.

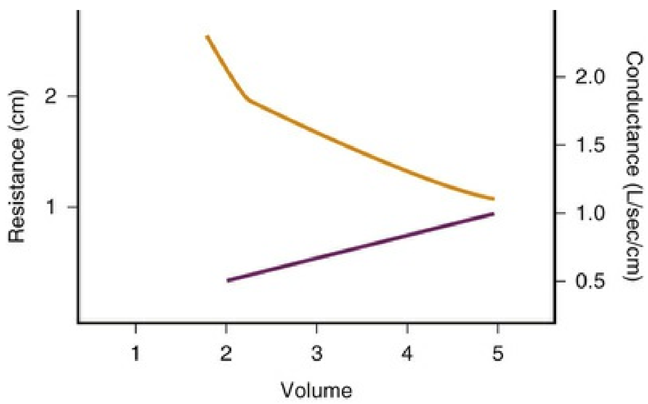

FIG. 45.3 Relationship between lung volume and airway resistance *(solid line)* and conductance *(dashed line)*. (Modified from Briscoe WA, Dubois AB. The relationship between airway resistance, airway conductance, and lung volume in subjects of different age and body size. J Clin Invest. 1958;37:1280.)

Dynamic Change in Airway Caliber During Respiration

Airway caliber is partially dependent on the transmural pressure. The transmural pressure is the difference between the interstitial pressure and atmospheric pressure. The external airway wall for the intrathoracic airways is subjected to the interstitial pressure, which is approximately equal to the pleural pressure. In contrast, the external walls of extrathoracic airways are subjected to atmospheric pressure. The intraluminal pressure is dependent on the generation of the airway. During inspiration, pleural pressure is negative relative to atmospheric pressure. Alveolar pressure is approximately equal to pleural pressure, and pressure at the mouth is equal to atmospheric pressure. This pressure difference creates a gradient from the

mouth to the alveoli. Extrathoracic airways tend to narrow during inspiration because the transmural pressure is positive. In contrast, the transmural pressure in the intrathoracic airways is negative, causing a tendency for these airways to dilate during inspiration. The degree of airway caliber change during inspiration depends on both the magnitude of the transmural pressure and airway wall compliance. At the end of inspiration there is a relaxation of the inspiratory muscles, and the elastic recoil of the respiratory system produces, relative to atmospheric pressure, a positive pleural and alveolar pressure. Because of the dynamic pressure changes previously described, there is a tendency for intrathoracic airways to narrow and extrathoracic airways to dilate during expiration.

Applied Forces

Ventilation of the lungs involves motion of the respiratory system, which is produced by the forces required to overcome the flow resistive, inertial, and elastic properties of the lungs and chest wall. Under normal circumstances, these forces are produced by the respiratory muscles.

If ventilation is to occur, opposing forces must be overcome by a pressure applied to the respiratory system to create motion. At each instant, the applied pressure (P_{APP}) must equal the sum of the pressure required to balance elastic recoil (P_{ER}) and the pressure lost to viscous (resistive) forces (P_R). The maximal pressures that can be generated by the respiratory muscles are determined by both lung volume and gas flow:

$$P_{APP} = P_{ER} + P_R$$

With use of the aforementioned equations, this may be converted to:

$$P_{APP} = (1/C)V + R\dot{V}$$

This equation is known as the *equation of motion of the respiratory system.*

Fig. 45.4 illustrates the pressure involved in respiration. Gradients must occur to allow for gas to flow into the lungs. The airway pressure gradient that drives airflow into the lungs is defined as:

$$P_M - P_{ALV}$$

where P_M is the pressure at the mouth, which is normally atmospheric, and P_{ALV} is the alveolar pressure. Transpulmonary pressure (P_{TP}) is defined as:

$$P_{TP} = P_{ALV} - P_{pl}$$

where P_{ALV} is the alveolar pressure and P_{pl} is the intrapleural pressure. P_{TP} is equal to elastic recoil of the lungs when there is no airflow. P_{TP} increases and decreases with

lung volume. Transchest wall pressure (P_{TC}) is defined as:

$$P_{TC} = P_{pl} - P_{bs}$$

where P_{pl} is the intrapleural pressure and P_{bs} is the pressure at the body surface that is usually atmospheric. P_{TC} and P_{pl} are equal in magnitude to the elastic recoil of the chest when there is no airflow and, like P_{TP}, they increase and decrease with lung volume.

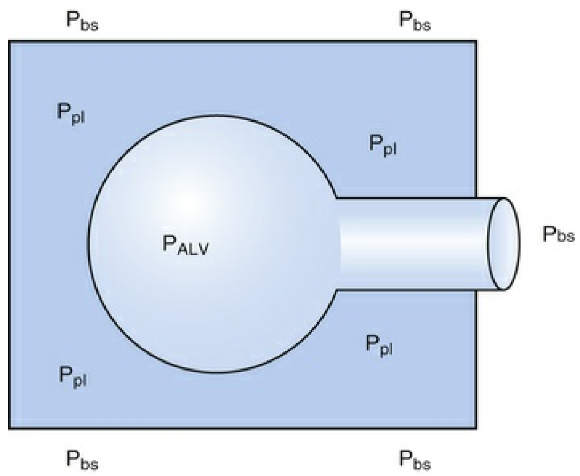

FIG. 45.4 Illustration of the pressure involved in respiration. Gradients must occur to allow for gas to flow into the lungs. P_{ALV}, alveolar pressure; P_{bs}, pressure at the body surface; P_{PL}, intrapleural pressure.

The transmural pressure (P_{RS}) is defined as:

$$P_{RS} = P_{ALV} - P_{bs}$$

where P_{ALV} is the alveolar pressure and P_{bs} is the pressure at the body surface. P_{RS} represents the transmural pressure across the entire respiratory system, including the lungs and the chest wall, and is equal to the net passive elastic recoil pressure of the whole respiratory system when airflow is zero.

During inspiration the respiratory muscles provide the applied pressure that expands the chest wall and lungs, causing the alveolar and airway pressure to fall. The net result is that the alveolar pressure becomes less than atmospheric pressure. Once alveolar pressure is less than atmospheric pressure, air flows into the lungs along a pressure gradient and the lungs inflate, storing potential energy in the elastic structures for expiration. In order for gas flow to occur, there must be a balance of forces. Table 45.1 illustrates these forces (expressed as pressures).

TABLE 45.1

Balance of Forces

$P_{RS} + P_{MUS}$	=	$P_L + P_{CW}$

$P_{ALV} - P_{bs} + P_{MUS}$	=	$P_L + P_{CW}$
Inspiratory muscle contraction		Lung, chest wall elastic recoil
Outward acting forces when positive		Inward acting forces when positive

Expiration is usually passive (excluding disease states where the patient actively tries to empty their lungs). That is, the energy stored in the elastic recoil of the lungs and the chest wall produces the positive alveolar and airway pressure needed to overcome flow resistance and air is forced from the lungs.

In order to inflate the lungs there must be an increase in alveolar pressure, which is usually done with positive pressure ventilation or a decrease in body surface pressure, such as in negative pressure ventilation (iron lung), or the respiratory muscles must be activated (normal breathing).

Under resting conditions, expiration is usually passive. At times of increased ventilatory requirements, such as during exercise, contraction of the abdominal and internal intercostals muscles can aid expiration.

Interactions Between Lungs and Chest Wall

The lungs and chest wall operate in series, and their compliance adds reciprocally to make total compliance:

$$1/C_T = 1/C_L + 1/C_{CW}$$

The chest wall is like a spring that may be either compressed or distended. Transthoracic pressure is negative at residual volume and at FRC, meaning the chest wall is smaller than its unstressed volume and its tendency is to spring out. Normal tidal breathing is entirely in the negative pressure range for transthoracic pressure. When examining the compliance curve of the chest wall (lung volume versus transthoracic pressure), pressure is 0 at about 65% of TLC. Thus the chest is at its unstressed volume and has no tendency to collapse or expand. Transthoracic pressure is positive at volumes above 65% TLC. The chest tends to collapse above its unstressed volume.

Volume-pressure loops observed during breathing are based on the flow resistance of gas and tissue. It had been previously suggested that the static volume-pressure relationship is represented by a single line, suggesting that the static pressures depend only on volume. However, the static pressure will vary depending on the volume history of the lung. Thus if the lung is fully expanded, at deep inspiration, static pressures will be lower. This concept is important because of the hysteresis of the lungs and tendency not to follow identical paths of response on the application and withdrawal of forces on the lung. Hysteresis applies to both the lung and chest wall.

Time Constant of Emptying

The time taken for volume in the respiratory system to be reduced by 63% when the respiratory system is allowed to empty passively and the volume-time profile is measured is known as the time constant (τ) of the respiratory system.[25] If we use a model of the respiratory system with a single compartment and a single, constant

elastance and a single, constant resistance, then the following occurs:

$$\tau = R/E$$

In a single compartment model the volume-time profile can be represented by a single exponential decay.

In healthy adults the time constant of the passive respiratory system is short—approximately 0.5 seconds. Such a short time constant allows the lungs to empty to the end-expiratory volume (EEV) at the end of each expiration. Thus the FRC and EEV are equal. Since the respiratory system is relaxed at the end of expiration, inspiration can begin as soon as inspiratory muscle activity is initiated. The expiratory time constant is shorter in children, with values approximating 0.3 seconds reported in infants with normal lungs.[26] Infants with hyaline membrane disease have stiffer than normal lungs with expiratory time constants reported as low as 0.1 seconds. In the case of patients with obstructive airway diseases such as asthma, resistance is increased and the expiratory time constant is longer. Therefore, a longer time is required for the lungs to empty and return the respiratory system to EEV. Patients with chronic airway obstruction frequently have carbon dioxide retention and an increased respiratory drive. This phenomenon results in an increased respiratory rate with a shorter respiratory cycle and less time available for expiration. In this situation the respiratory system frequently does not have time to return to EEV before the next inspiration starts; thus FRC occurs at a volume higher than EEV, not equal to EEV, which prevents relaxation of the respiratory system at the end of expiration. This lack of relaxation of the respiratory system at the end of expiration causes a positive recoil pressure. This pressure is called *intrinsic positive end expiratory pressure,* or $PEEP_i$. Before inspiratory flow can begin, the patient's inspiratory muscle must produce enough force to overcome the $PEEP_i$; thus this force is "lost" to produce inspiratory flow and represents a load that must be overcome by the inspiratory muscle. In patients with severe airway obstruction, this pressure can be as high as 15 to 20 cm H_2O.

Physiology of Positive Pressure Mechanical Ventilation

Up to this point our discussion has focused on patients breathing spontaneously without artificial support. To understand the respiratory physiology principles that apply to the critically ill pediatric patients, we must briefly examine the effects of positive pressure breathing on the pediatric respiratory system.

The respiratory system, like most biological systems, is closely associated with exponential functions. An exponential function is a mathematic expression that describes an event where the rate of change of one variable is proportional to its magnitude.

For example, in a passive breath, expiratory flow will be higher at the beginning of expiration than at the end, as the lung volume decreases toward FRC.

Among various forms of exponential functions, the two most important ones for the clinician in mechanical ventilation are the rising and decaying exponential

functions.

Rising exponential function expresses an increase of one variable as a function of time—for example, flow, pressure, or volume versus time. A rising exponential function expresses the behavior of a physical system where the rate of change of one variable is proportional to its magnitude and a constant. In this relationship, the largest rate of change is always observed at the beginning of the event, and the smallest rate of change is always observed at the end of the event.

Decaying exponential function expresses a decrease of one variable as a function of time: flow, pressure, or volume versus time. An example of this relationship can be seen with the pressure decrease during lung deflation in a passive expiration. Flow returns to a baseline during a passive expiration, reflecting a negative decaying function. This expression of a physical system is expressed where the rate is proportional to its magnitude only. Therefore the rate of change will always have the largest value at the beginning of the event and the smallest value at the end of the event. The rate of decay is not constant over time.

As previously discussed, the respiratory system is governed by various laws of physics that describe the various dynamic forces involved in the movement of the system. In physiology, force is measured as Pressure = Force/Area, displacement is measured as Volume = Area × Displacement, and the relevant rate of change is measured as flow (eg, Average flow = ΔV/ΔTime; Instantaneous flow = dv/dt [the derivative of volume with respect to time]). The pressure necessary to cause flow of gas into the airway and increase the volume of the gas in the lung is the key component in positive pressure mechanical ventilation. The volume of gas (ΔV) to any lung unit and the gas flow *(* $\dot{V}$ *)* is related to the applied pressure (ΔP) by:

$$\Delta P = (\Delta V/C) + \dot{V} \times R + K$$

where *R* is the airway resistance and *C* is the lung compliance. This equation is the same one previously described as Newton's equation of motion for the respiratory system. The applied pressure to the respiratory system measured at the inlet is the sum of the muscle pressures P_{mus} (pressure generated by the patient's spontaneous muscular forces) and the ventilator pressure $P_{applied}$ (pressure generated by ventilator). Muscle pressure is patient generated but cannot be directly measured. Muscle pressure represents the pressure generated by the patient to expand the thoracic cage and lungs. In contrast, ventilator pressure is the transrespiratory pressure generated by the ventilator during inspiration. Combinations of these pressures are generated when a patient is breathing on a positive pressure ventilator. In spontaneously breathing patients, the pressure measured at the patient's airway is a mix of the two pressures dependent on the mode of ventilator support used. For example, in continuous positive airway pressure, all pressure generated will be by the patient muscles, whereas in pressure support, the pressure generated will be a mix of the pressure generated by the patient's respiratory muscles and that generated by the ventilator. When respiratory muscles are at complete rest, the muscle pressure is zero; therefore the ventilator must generate all the pressure necessary to deliver the tidal volume and inspiratory flow. The reverse is also true, and there are degrees of support depending on the amount of force generated by the patient's respiratory muscles. The application of the equation of motion to the

generation of gas flow is the next important step. Total pressure applied to the respiratory system (P_{RS}) of a patient undergoing ventilation is the sum of the pressure generated by the ventilator (measured at the airway) (P_{AO}) and the pressure generated by the respiratory muscles (P_{MUS}). Therefore:

$$P_{RS} = P_{Applied} + P_{MUS} = (V/C) + \dot{V} \times R + K$$

where P_{RS} is the respiratory system pressure, $P_{Applied}$ is the applied pressure by the ventilator, P_{MUS} is the pressure developed by the respiratory muscles, $\dot{V}$ is flow, R is airway resistance, V/C is respiratory system compliance, and K is the pressure. $P_{Applied}$ and $\dot{V}$ can be measured by the pressure and flow transducer in the ventilator. Volume is derived mathematically from the integration of the flow waveform.

To generate a volume displacement, the total forces have to overcome elastic and resistive elements of the lung and airway/chest wall represented by V/C and V × R, respectively. V/C depends on both the volume insufflated in excess of resting volume and the respiratory system compliance. To generate gas flow, the total forces must overcome the resistive forces of the airway and the endotracheal tube against the driving pressure gradients. At any moment during inspiration, there must be a balance of forces opposing lung and chest wall expansion measured as the airway pressure (P_{AO}). The opposing pressure can be summarized as the sum of elastic recoil pressure ($P_{elastic}$), flow-resistive pressure ($P_{resistive}$), and inertial pressure ($P_{resistance}$) of the respiratory system. Therefore:

$$P_{AO} = P_{elastic} + P_{resistive} + P_{inertance}$$

Inertial forces are usually negligible during conventional ventilation, which depends on bulk convective flow—unlike in high-frequency ventilation, where volumes are at the level of dead space. Therefore, for conventional ventilation, the forces exemplified in the equation of motion can expressed as:

$$P_{AO} = P_{elastic} + P_{resistive}$$

If elastic forces are recognized as the product of elastance and volume ($P_{elastic}$ = E × V) and the resistive forces as the product of flow and resistance (Resistive $\dot{V}$ × R), the formula can be written as:

$$P_{AO} = (\text{Elastance} \times \text{Volume}) + (\text{Resistance} \times \text{Flow})$$

If compliance (the inverse of elastance) is substituted for elastance, the equation of motion, as described in the preceding text, becomes:

$$P_{AO} = \text{Volume/Compliance} + \text{Resistance} \times \text{Flow}$$

The quotient of volume displacement over compliance of the respiratory system represents the pressure necessary to overcome the elastic forces above the resting lung volume or FRC. It is essential to remember that the pressure to distend the alveoli is inversely related to the size of the alveoli. Thus, if the lung volume is below the resting volume, more pressure must be generated to distend those alveoli. This is reflected as La Place's law, and the resting lung represents the quantity of air remaining in the lungs at the end of a spontaneous expiration. Of course, just as in so many aspects of medicine, this is not as clear as it appears. The reader must remember that La Place's law is applied to spheres. Alveoli are thought to be prismatic or polygonal in shape (ie, their walls are flat), and Laplace's law considerations in their inflation apply only to the very small curved region in the fluid where these walls intersect. Even though it has been invoked as a mechanical model for the forces of alveolar inflation and as an explanation for the necessity of pulmonary surfactant in the alveolus, it still represents a reasonable model for alveolar behavior and consequences of lack of recruitment of the lung.

Pressure, flow, and volume are all measured relative to their baseline values. The pressure necessary to cause inspiration is measured as the change in airway pressure above PEEP. For example, in a patient breathing spontaneously on continuous positive airway pressure, the ventilator pressure is zero; the patient must use his or her respiratory muscles to generate all the work of breathing. The same can be applied to the volume during inspiration or the tidal volume, which is the change in volume above FRC. The pressure necessary to overcome the resistive forces of the respiratory system is the product of the maximum airway resistance (R_{MAX}) and inspiratory flow. Flow is measured relative to its end-expiratory value, which is usually zero, unless a $PEEP_i$ is present. The ultimate result of the gas movement or flow is to allow gas to reach and be exchanged at the alveolar unit.

Gas Exchange

The basic function of the respiratory system is to supply oxygen to the body and to remove excess carbon dioxide. The following are the essential steps involved in this process:

1. Ventilation, the exchange of gas between the atmosphere and alveoli

2. Diffusion across the alveolar-capillary membrane

3. Transport of gases in the blood

4. Diffusion of the gases from the capillaries of the systemic circulation to the cells of the body

5. Use of the oxygen and production of carbon dioxide within the cells as a byproduct of metabolism

During the process of ventilation, air is transported back and forth between the outside of the body and the terminal respiratory units of the lungs. In the alveoli, the air is exposed to a thin film of blood. O_2 diffuses across the alveolar-capillary

membrane, enters the blood, and combines with hemoglobin. Simultaneously, CO_2 diffuses from the blood and enters the alveolar gas. In this way, the mixed venous blood entering the lungs is altered through the addition of O_2 and removal of CO_2. This is the process of gas exchange.

The partial pressure of O_2 (PaO_2) and CO_2 ($PaCO_2$) in the arterial blood, and therefore the adequacy of gas exchange, is dependent on a number of factors. These factors include the composition of the alveolar gas and the extent to which equilibrium is reached between the alveolar gas and pulmonary capillary blood. The alveolar gas composition is, in turn, dependent on the content of the inspired air and mixed venous blood, the quantity of air (ventilation) and blood (perfusion) reaching the alveoli, and the ratio of alveolar ventilation to perfusion ($\dot{V}_A/Q$). Of the factors determining the adequacy of gas exchange, the structure and function of the lungs primarily influence the ventilation-perfusion relationships, alveolar ventilation, and diffusion of O_2 and CO_2. Alveolar ventilation and oxygenation are related by the alveolar gas equation. The alveolar air equation for calculating P_AO_2 is essential to understanding any PaO_2 value and in assessing if the lungs are properly transferring oxygen into the blood. This is discussed further as follows in regard to its relation to ventilation and perfusion.

$$P_AO_2 = F_iO_2 * (P_B - P_{H2O}) - P_aCO_2/RQ$$

P_AO_2	The alveolar partial pressure of oxygen (pO_2)
F_IO_2	The fraction of inspired gas that is oxygen (expressed as a decimal)
P_B	Barometric pressure
P_{H2O}	The saturated vapor pressure of water at body temperature and the prevailing atmospheric pressure
P_aCO_2	The arterial partial pressure of carbon dioxide (pCO_2)

The respiratory quotient or respiratory coefficient (RQ) is the ratio of CO_2 produced to the O_2 consumed, and its value is typically 0.8.

Ventilation Perfusion Relationships

In the normal, upright lung, both alveolar ventilation and perfusion increase from the apex to the bases largely because of the effects of gravity. Blood flow increases more rapidly from apex to base than ventilation, and therefore $\dot{V}_A/Q$ ratios are high at the apex and decrease progressively toward the base of the lungs. The regional differences in perfusion are called *West's zones of perfusion*.[27-29] West's zone I occurs when mean pulmonary arterial pressure is less than or equal to alveolar pressure; thus no blood flow occurs. In zone I, the apices of the lung of an upright adult, there are unperfused yet ventilated alveoli, which is dead space ventilation. (Bronchial arterial flow nourishes the lung.) In zone II, which consists of the mid lung, pulmonary artery pressure is greater than alveolar pressure. Conditions in this zone are governed by the fact that blood flow is not influenced by venous pressure but by the difference between arterial and alveolar pressures, which is a function of (hydrostatic) height. In zone III, the lower zone of the lung, pressure at the alveolus is exceeded by the pressures in both pulmonary artery and vein. Flow in this zone is a function of pulmonary artery and pulmonary venous pressures and is independent

of height. At the base of the lung, because of higher perivascular pressures and reduced lung expansion, flow is again diminished.[30]

Any disorder affecting the airways or the parenchyma of the lung will result in an increased imbalance between ventilation and perfusion and therefore a greater than normal range of $\dot{V}_A/Q$ ratios. The presence of varying $\dot{V}_A/Q$ ratios, whether in the normal or the diseased lung, has several important effects on gas exchange. The PO_2 and the PCO_2 of an alveolus, and therefore of the capillary blood leaving it, is dependent on the ratio of ventilation to perfusion. As this ratio decreases, the PO_2 decreases and the PCO_2 increases. The opposite occurs as the $\dot{V}_A/Q$ ratio increases. Fig. 45.5 demonstrates the relationship between the ventilation/perfusion ratios P_AO_2 and P_ACO_2.

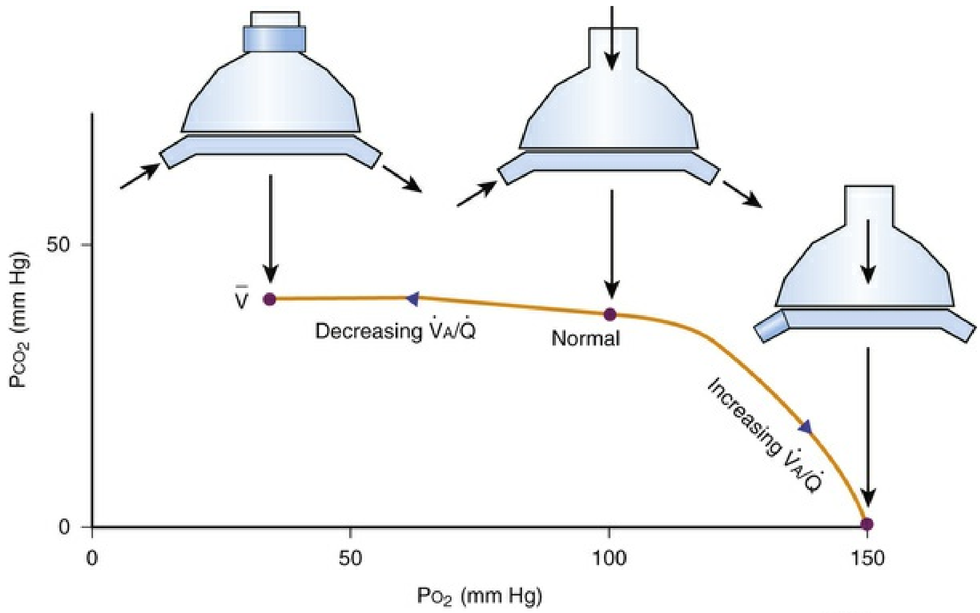

FIG. 45.5 Relationship between the ventilation/perfusion ratio *($\dot{V}_A/Q$)* of an alveolus and the PO_2 and PCO_2 of the alveolar gas and end-capillary blood. The PO_2 and PCO_2 vary from the mixed venous blood *($\dot{V}$)* to inspired air *(I)* as $\dot{V}_A/Q$ changes from zero to infinity. (Modified from West JB. Ventilation blood flow and gas exchange. 3rd ed. Oxford, England: Blackwell Scientific; 1977:37.)

Lung units with low $\dot{V}_A/Q$ ratios therefore decrease arterial PO_2 and increase arterial PCO_2. In the extreme cases in which no ventilation reaches a lung unit, $\dot{V}_A/Q$ is zero and mixed venous blood is added unchanged to the arterial circulation. A right-to-left shunt occurs. The contribution of low $\dot{V}_A/Q$ units and shunts to arterial blood may be determined through the calculation of the venous admixture Q_S/Q_T:

$$Q_S/Q_T = (C_C - C_a)/(C_C - C\bar{V}),$$

where C_c, C_a, and $C\bar{V}$ are the O_2 contents of pulmonary end-capillary, arterial, and

mixed venous blood, respectively. This contribution also may be assessed by calculating the difference between the alveolar and arterial PO_2 ($A - aDO_2$), which varies directly with the extent of venous admixture. Because of difficulties in accurately measuring it, the mean alveolar PO_2 (P_AO_2) is calculated from the alveolar air equation:

$$P_AO_2 = P_IO_2 - PCO_2/R,$$

where P_IO_2 represents the PO_2 of inspired air and R is the respiratory exchange quotient—the ratio of CO_2 production to O_2 consumption. In healthy young subjects, the $A - aDO_2$ averages 8 mm Hg.[31]

When ventilation to a lung unit exceeds its perfusion (that is, $\dot{V}_A/Q$ >1), the excess ventilation is considered to be "wasted" because it does not participate in gas exchange. The sum of the excess ventilation contributed by lung units with high $\dot{V}_A/Q$ ratios is referred to as *alveolar dead space*.

The effects of increasing ventilation/perfusion imbalance on gas exchange are that as the amount of inequality increases, both the ratio of physiologic dead space to tidal volume and venous admixture increases and arterial PO_2 falls. Arterial PCO_2 also progressively increases.

Alveolar Ventilation

The volume of air entering the lungs each minute that actually participates in gas exchange is called the *alveolar ventilation* ($\dot{V}_A$). It is therefore the difference between the total volume of air entering the lungs each minute (minute ventilation, $\dot{V}_E$) and the volume of air entering the lungs that does not participate in gas exchange (dead space: $\dot{V}_D$): $\dot{V}_A = \dot{V}_E - \dot{V}_D$.

The type of dead space ($\dot{V}_D$) depends on the location of the volume not exchanged, either in the anatomic airways or in the alveolus. The anatomic dead space is equal to the volume of airways proximal to the terminal respiratory units. Approximately 25% of each tidal volume is lost in these conducting airways. The ultimate volume is dependent on body size and equals approximately 1 mL/lb.[32] This volume is divided almost equally between the upper and lower airways. An alveolar dead space is produced by all alveoli that are overventilated relative to their perfusion. Thus, more gas is available than blood for diffusion. The physiologic dead space is usually expressed as a fraction of the tidal volume (V_D/V_T).

The alveolar ventilation is an important determinant of gas exchange because it, along with the rate at which tissue metabolism produces CO_2 ($\dot{V}_{CO2}$), determines the PCO_2 of arterial blood:

$$PCO_2 = \dot{V}_{CO2}/\dot{V}_A$$

When $\dot{V}_{CO2}$ is constant, P_{CO_2} varies inversely with $\dot{V}_A$. It is evident that at given minute ventilation, the P_{CO_2} will vary directly with the amount of physiologic dead space. As dead space changes, the P_{CO_2} can be kept constant only by increasing or decreasing $\dot{V}_E$ by an identical amount.

The measurement of dead space has evolved from the original description by Bohr in 1891 when dead space was considered simply the gas from the conducting airways. One can calculate the physiologic dead space as:

$$V_D/V_T = (Pa_{CO2} - P\bar{E}_{CO2})/Pa_{CO2}$$

where $P\bar{E}_{CO2}$ is end-tidal P_{CO_2}.

Diffusion of Oxygen and Carbon Dioxide

Gas must travel through a number of barriers between the alveolus and blood. These barriers include the alveolar epithelial lining, basement membrane, capillary endothelial lining, plasma, and red blood cell. The amount of gas (Q) diffusing through a membrane is directly proportional to the surface area available for diffusion (S), the pressure difference for the gas on either side of the membrane (p1 − p2), and a constant (K) that depends on the solubility coefficient of the gas, membrane characteristics, and liquid used. This association is defined by the Fick principle of the diffusion state as follows:

$$Q/\text{min} = KA(p1 - p2)/d$$

where *Q* is inversely proportional to the distance it has to diffuse, whereas *K* is proportional to the solubility of the gas and inversely proportional to the square root of the molecular weight.

In healthy subjects at rest, equilibration of the P_{O_2} and P_{CO_2} of the alveolar gas and pulmonary capillary blood is achieved in approximately 0.75 seconds.[33] This is about one-third of the time spent by the blood in the capillary network. The rate of pulmonary blood flow can increase greatly, to the point that it prevents equilibration. For this reason, diffusion disequilibrium has been demonstrated in healthy persons, but only during strenuous exercise at high altitudes.

In the presence of parenchymal disease, diffusion impairment may occur solely as a result of thickening of the alveolar-capillary membrane. Much more commonly, however, diffusion disequilibrium is associated with destruction of the pulmonary capillary bed. This destruction results in a greatly increased blood flow velocity in the remaining capillaries, which may allow insufficient time for equilibration. Even when parenchymal disease is severe, however, diffusion disequilibrium usually occurs only when cardiac output, and therefore rate of flow, is markedly increased.

CHAPTER 46

Noninvasive Respiratory Monitoring and Assessment of Gas Exchange

Beryl F. Yaghmai, Kenneth A. Schenkman

PEARLS

- Pulse oximetry is based on the principles that the pulsatile component of the optical absorbance detected from tissue is primarily from arterial blood and that oxyhemoglobin and reduced (deoxy-) hemoglobin have different optical absorption spectra.
- Limitations of pulse oximetry include motion artifact, effects of ambient light, presence of pigmentation or dyes, low perfusion states, and dyshemoglobinemia.
- Most pulse oximeters measure only oxyhemoglobin and deoxyhemoglobin; however, blood cooximeters and noninvasive cooximeters now account for other absorbing species such as methemoglobin and carboxyhemoglobin.
- Capnography can be a good global indicator of the patient's condition and can detect alveolar hypoventilation before changes detected by pulse oximetry.
- The accuracy of the capnogram depends on the sampling site. If the tidal volume is small and the sample flow rate is large, the gas sample may be diluted by entrained fresh gas.

Noninvasive monitoring in the form of vital signs (ie, heart rate, respiratory rate, noninvasive blood pressure, fluid intake and output, and temperature) has been used routinely for all patients receiving care in the ICU since the birth of the specialty. Guidelines for equipment and monitoring and for levels of care for pediatric ICUs (PICUs) were specified by the American College of Critical Care Medicine in 2004.[1] The majority of children admitted to the PICU present with

cardiorespiratory disease or with an acute illness that may progress to involve the respiratory system, emphasizing the specific need for careful monitoring of respiratory parameters. Close respiratory examination and monitoring allow titration of therapies to minimize oxygen toxicity, ventilator-induced injury, optimize patient-ventilator interaction, and aid in weaning from the ventilator.[2] Pulse oximetry and capnometry have significantly affected the practice of critical care medicine and are now standards of care. New technologies currently under development to noninvasively monitor physiologic function may significantly decrease the need for more invasive monitoring and lessen the associated risks of such modalities.

Pulse Oximetry

Pulse oximetry is a significant technologic advance that has improved patient safety.[2-6] Its ease of application and accuracy have resulted in widespread use, and it is now a standard monitoring modality for many aspects of medical care. Indications for pulse oximetry monitoring in the pediatric population now include screening for neonatal congenital heart disease.[7-9] In the ICU, pulse oximetry is used to detect hypoxia and wean the oxygen concentration in patients undergoing mechanical ventilation.

Takuo Aoyagi, working for the Nihon Kohden Corporation in Japan, first proposed the theory for pulse oximetry in 1972. His idea was developed into a working oximeter, which subsequently was patented in Japan in 1974 and marketed as the world's first commercial pulse oximeter. In 1977 a fiberoptic-based pulse oximeter with improved accuracy was marketed by Minolta, and in 1982 Nellcor began marketing a pulse oximeter that ultimately became an industry standard.[10] Since then numerous companies have produced and marketed pulse oximeters, and improvements in technology continue to improve the accuracy and reliability of these devices. More recently, Masimo Corporation (Irvine, Calif.) introduced pulse oximeters with signal extraction technology[11] that minimizes motion artifact and interference from ambient light and is able to function in relatively low perfusion states. This approach has improved the accuracy of pulse oximetry readings and has decreased the frequency of false alarms in clinical settings.[12-16]

Standard pulse oximeters are not accurately calibrated for the low saturations seen with some congenital cardiac lesions. There is, however, a “blue” sensor that is particularly sensitive in patients with cyanotic congenital heart disease.[17] Accurate pulse oximetry is especially vital in the neonatal population, who benefit from tight control of oxygenation in order to minimize oxidative stress and to decrease the risk of retinopathy of prematurity.[18]

Principles of Pulse Oximetry

Pulse oximetry is based on the principles that (1) the pulsatile optical absorbance detected in biological tissue is primarily due to arterial blood and that (2) oxyhemoglobin and reduced (deoxygenated) hemoglobin have different optical absorption spectra.[3] The attenuation of light passing through blood-perfused tissue changes with pulsation of blood and the alternating component of the light

attenuation results from the composition of arterial blood.[19] Fig. 46.1 is a schematic diagram showing that the component of light attenuation as a result of pulsatility comes from arterial blood. This information can be analyzed to determine the hemoglobin saturation in the arterial blood. Absorption of light as a result of other tissue components and capillary and venous blood in the static (nonpulsatile) portion of the signal is ignored in the analysis.

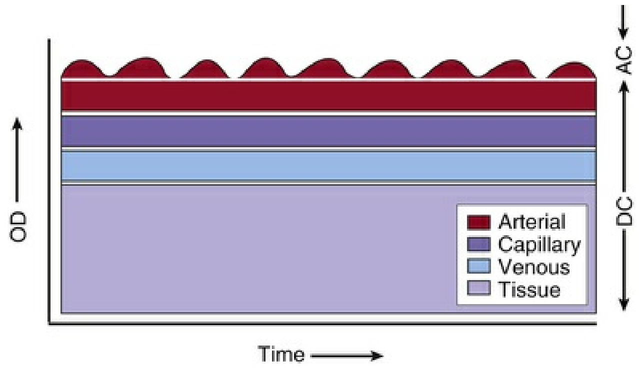

FIG. 46.1 Light passing through a pulsating tissue will be absorbed by multiple components of tissue and blood. The alternating component (AC) is composed of only arterial blood.

Light passing through a turbid media such as tissue is attenuated by absorption and scattering. If light scattering in tissue is assumed to be fairly constant, then measured changes in the attenuation of the transmitted light can be assumed to result from changes in absorption. Beer's law describes the theoretic absorption of light as follows:

$$\text{Absorbance (OD)} = -\log_{10}(I/I_O) = \varepsilon bc \quad \textbf{Eq. 46.1}$$

where I is light emerging from the sample, I_o is incident light illuminating the sample, ε is molar extinction coefficient of the specific absorbing species at a specific wavelength, b is path length (in centimeters) the light traverses, and c is molar concentration of the absorbing species. Thus changes in the concentration of an absorber, that is, oxyhemoglobin, result in changes in absorbance.

Hemoglobin has characteristic light-absorbing properties that change with oxygen binding. Fig. 46.2 shows absorption spectra of oxyhemoglobin and deoxyhemoglobin in the visible and near-infrared spectral region. At any given wavelength there is a difference in absorption between oxyhemoglobin and deoxyhemoglobin except where the spectra cross at wavelengths called *isosbestic wavelengths,* where the absorption is the same for each state. At nonisosbestic wavelengths, the difference in absorption can be used to determine the fraction of oxyhemoglobin. Saturation of hemoglobin is defined as follows:

$$Hb_{sat} = [OxyHb]/([OxyHb]+[DeoxyHb]) \quad \textbf{Eq. 46.2}$$

where Hb_{sat} is fractional saturation of hemoglobin, [*OxyHb*] is concentration of oxyhemoglobin, and [*DeoxyHb*] is concentration of deoxyhemoglobin. Hemoglobin percent saturation, as commonly reported, is determined by multiplying Hb_{sat} by 100.

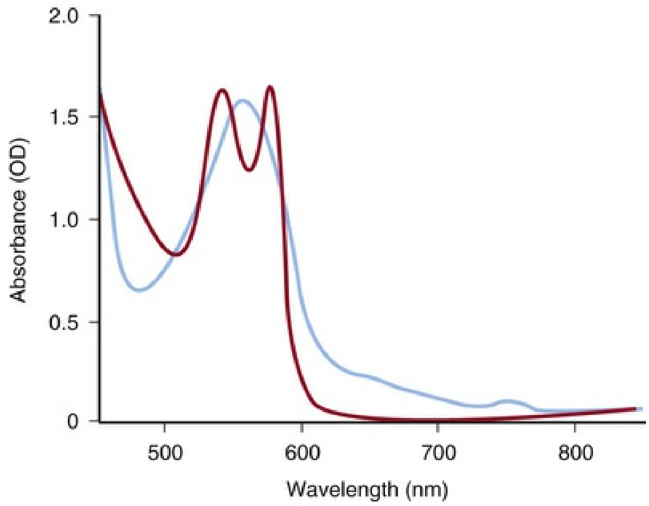

FIG. 46.2 Absorption spectra of hemoglobin in the visible and near-infrared spectral region. The deoxy form of hemoglobin (blue) has a single peak in the visible and near-infrared region. Oxyhemoglobin (red) has two peaks in the visible region but no significant peak in the near-infrared region.

Pulse oximeters typically use red (660-nm) and infrared (940-nm) wavelengths of light to determine the ratio of oxygenated to deoxygenated blood.[11] Deoxygenated blood absorbs more red light, whereas oxygenated blood absorbs more infrared light. The two wavelengths are passed through an arterial bed, and the ratio of infrared and red light transmitted to the photodetector is determined. The absorption around 940 nm is relatively low and fairly constant over the range of saturations; thus a change in absorbance at 660 nm can be referenced to the absorption at the 940-nm wavelength and is used to determine the saturation. The ratio is calibrated against measurements of arterial oxygen saturations from human volunteers and their absorbance ratios. Each pulse oximeter uses a complex algorithm to convert the change in absorbance at the two wavelengths to an absolute saturation value. More wavelengths can be used to improve the accuracy of the measurement.

In the presence of other forms of hemoglobin, primarily carboxyhemoglobin or methemoglobin, the saturation of hemoglobin is correctly determined by the more complex relationship:

$$\mathrm{Hb_{sat}} = [\mathrm{OxyHb}]/([\mathrm{OxyHb}] + [\mathrm{DeoxyHb}] + [\mathrm{MetHb}] + [\mathrm{CarboxyHb}]) \qquad \textbf{Eq. 46.3}$$

where [*MetHb*] is concentration of methemoglobin and [*CarboxyHb*] is concentration of carboxyhemoglobin. Most pulse oximeters cannot accurately account for the

presence of these other forms of hemoglobin. Blood cooximeters, however, do account for these species, as do the newer Masimo pulse oximeters.

Validation

Numerous studies have been performed to validate existing pulse oximeters.[20,21] Pulse oximeters also must be subjected to extensive testing before obtaining US Food and Drug Administration (FDA) approval for marketing in the United States. Despite all of the current testing, difficulties in both calibration and validation remain. One of the most significant issues surrounding calibration is the development of an appropriate universal test that will accurately test the pulse oximeter for a wide range of potential clinical applications. Pulse oximeters must be accurate for a wide range of skin thickness and color and over a wide range of saturations. In general, pulse oximeters are most accurate at higher saturations, usually above 75%.[22-24]

Sources of Error

Although pulse oximetry is widely accepted as a valid clinical monitor and provides valuable minute-to-minute clinical data, pulse oximeters are subject to multiple potential sources of error. Pulse oximetry measures oxygen saturation (SaO_2). SaO_2 and PaO_2 are not linearly related; the oxyhemoglobin dissociation curve is sigmoid in shape (Fig. 46.3). Large changes in PaO_2 at high levels of oxygen, the upper flat portion of the oxyhemoglobin dissociation curve, occur with little change in saturation. Saturations measured by pulse oximetry on average overestimate SaO_2 in the range of 76% to 90%,[25] and the accuracy of pulse oximetry falls with arterial oxygen saturations less than 70%.[2,3] At arterial oxygen saturations below 70%, pulse oximetry may be more appropriate for showing trends.[3]

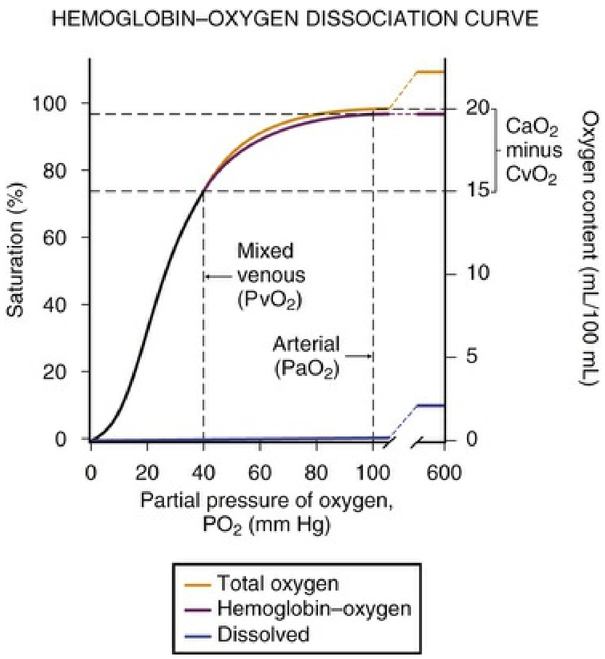

FIG. 46.3 Hemoglobin-oxygen (Hb-O_2) dissociation curve shows the percentage saturation of hemoglobin at each Po_2. When the hemoglobin concentration is known, the content of oxygen can be calculated. The total content includes the small additional content of oxygen in solution, which becomes significant at high levels of Po_2. The saturation scale on the left applies only to the Hb-O_2 line. The scale on the right shows content values for a normal hemoglobin level of 15 g/100 mL blood. (Modified from Hlastala MP. Blood gas transport. In: Culver BH, ed. The Respiratory System. Seattle: ASUW Publications; 1997. Redrawn in Albert RK, Spiro SG, Jett R, eds. Clinical Respiratory Medicine. 2nd ed., St. Louis: Mosby Elsevier; 2004.)

Pulse oximetry sensors may be unable to distinguish a true signal from background in low perfusion states that result in diminished pulsations (eg, vasoconstriction, low cardiac output, and hypothermia).[26] This situation is usually displayed as an inadequate pulse message.[2] Low peripheral perfusion and motion artifact are the most common causes of inaccurate pulse oximetry readings.[6,11,27] Newer designs of pulse oximeters with signal-progressing algorithms that detect and ignore motion and pulse rate interferences help overcome these limitations.[11,27]

Other sources of error include interfering dyes or other pigments in the blood and ambient light.[26] Intravenous dyes and certain colors of nail polish may falsely lower pulse oximetry readings. The extent of ambient light interference has been questioned for some of the pulse oximeters studied,[28] and shielding of the probe from ambient light is often used clinically to improve performance.

The presence of dyshemoglobinopathies is an infrequent clinical problem but can result in erroneous pulse oximetry readings.[26] Abnormal hemoglobin levels (carboxyhemoglobin, methemoglobin) that have similar absorbance spectra can lead to overestimation of the true SaO_2.[3] In methemoglobinemia, the iron in the heme groups in hemoglobin becomes oxidized from the ferrous (Fe^{2+}) state to the ferric (Fe^{3+}) state. The oxidized form of hemoglobin, called methemoglobin, cannot bind oxygen. Thus the presence of significant quantities of methemoglobin leads to tissue hypoxia because these molecules no longer participate in oxygen transport. However, light absorbance by methemoglobin more closely resembles oxyhemoglobin than deoxyhemoglobin at the measured wavelengths, erroneously leading the pulse oximeter to indicate a higher percentage of oxygen saturation than expected.[29,30] Similarly, the presence of carboxyhemoglobin may result in erroneous reading in pulse oximetry because carbon monoxide–bound hemoglobin also does not participate in oxygen transport.[31]

Masimo has developed a pulse oximeter, known as the Masimo Rainbow SET, that uses eight wavelengths of light (Fig. 46.4) and thus is able to determine carboxyhemoglobin and methemoglobin levels in addition to oxygenated and deoxygenated hemoglobin.[32] Because these other species of hemoglobin are recognized, it is also possible to have a continuous readout of total hemoglobin. The Rainbow oximeter will be useful not only for monitoring patients with dyshemoglobinemias but also in situations where occult blood loss may be occurring because of its ability to report total hemoglobin. Because the technology is relatively new, confirmation with laboratory samples may still be necessary, but trends can then be followed with the oximeter, minimizing the need for blood sampling.[33]

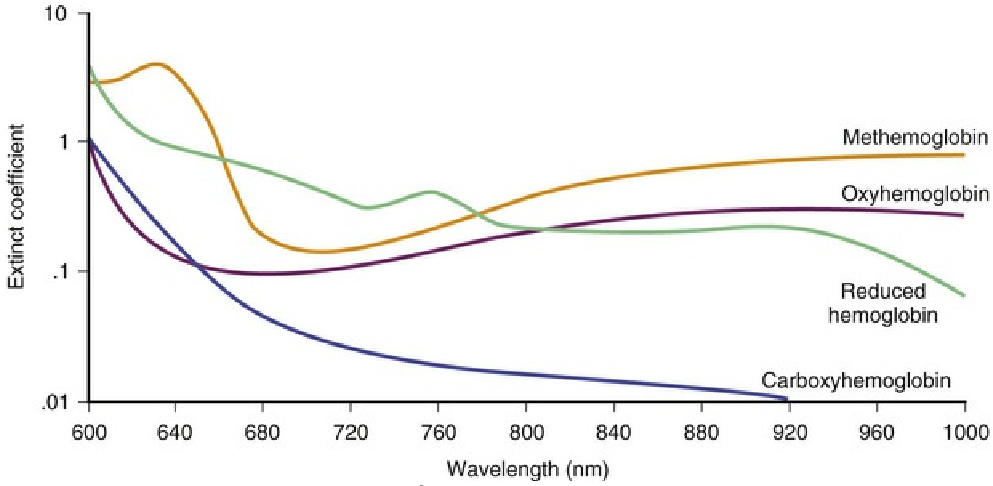

FIG. 46.4 Absorption spectra for carboxyhemoglobin, deoxyhemoglobin, oxyhemoglobin, and methemoglobin used in the Masimo SET Rainbow pulse oximeter. (Modified with permission from Masimo Corporation.)

Because cooximeters account for the presence of both carboxyhemoglobin and methemoglobin, blood gas samples sent for cooximetry should correctly measure hemoglobin saturation in cases where measurable levels of either methemoglobin or carboxyhemoglobin are present or suspected. Fetal hemoglobin has a sufficiently similar absorbance spectrum to adult hemoglobin, such that the presence of fetal hemoglobin does not significantly affect the determined saturation.[34] The presence of bilirubin also does not appear to significantly affect pulse oximetry readings.[35]

Probe Placement

Pulse oximetry probes typically are placed on fingers or toes, with the light-emitting diodes placed across the digit, opposite from the detector. For premature and small infants, the probe often is placed around the entire palm or foot with good results. In larger pediatric patients the nasal ala may also be used.[36] Because of scattering of light in tissue, pulse oximeter probes also can be used in a reflectance mode. In this manner, both light-emitting diodes and detectors are on the same surface and can be placed, for example, on the forehead.[37,38] Transesophageal probes have been designed and are used for care of operative or critically ill patients with potentially poor peripheral perfusion.[39-41] The complications of pulse oximetry are rare. They include skin burns and pressure necrosis in newborns.[2,3] Limited understanding of pulse oximetry by health care providers may be an underrecognized problem, along with time spent determining whether alarms are false.[6,42]

Capnometry and Capnography

Another monitoring technology routinely used in the critical care unit is the measurement of carbon dioxide (CO_2). Capnometry is the measurement of the partial pressure (or concentration) of CO_2 in the patient's airway during the entire ventilatory cycle. A capnometer provides a numeric measurement of inspired and expired, end-tidal CO_2 (P_{ETCO_2}). Capnography is the graphic display of the partial pressure or concentration of CO_2 as a waveform (capnogram), usually plotted as

PCO_2 versus time. When the waveform display is calibrated, capnography includes capnometry.

Physiologic Basis

$PETCO_2$ monitoring is the noninvasive measurement of exhaled carbon dioxide at the plateau of the carbon dioxide waveform. $PETCO_2$ concentration reflects $PaCO_2$, cardiac output, percentage of dead space, and airway time constants. In healthy subjects, the $PETCO_2$ concentration is 1 to 5 mm Hg less than the $PaCO_2$.[43] $PETCO_2$ concentration represents the PCO_2 of all ventilated alveoli, whether or not they are perfused. Therefore any condition that reduces pulmonary perfusion of ventilated alveoli increases the difference between $PaCO_2$ and $PETCO_2$. When ventilation and perfusion are well matched throughout the lung, the arterial partial pressure of CO_2 ($PaCO_2$) and the partial pressure of $PETCO_2$ are nearly equal, normally 40 mm Hg. If a discrepancy between ventilation and perfusion exists, a difference between the $PaCO_2$ and $PETCO_2$, also known as (a-et)ΔPCO_2, occurs. Comparison between $PETCO_2$ concentration and $PaCO_2$ helps to differentiate between change in alveolar ventilation, CO_2 production, or pulmonary perfusion as a cause of the change in $PETCO_2$ concentration.

The capnogram displays the CO_2 concentration in the patient's airway over time (Fig. 46.5). The essentials of a normal capnogram are (1) zero baseline during early exhalation, which reflects gas exhaled from the anatomic dead space; (2) sharp upstroke during midexhalation, which reflects the transition to alveolar gas; (3) relatively horizontal alveolar plateau (the final peak is also known as $PETCO_2$ [or end-tidal CO_2] because it reflects the end of expiration; prolonged exhalation caused by obstructive lung disease causes a steeper plateau); and (4) sharp downstroke and return to a zero baseline at the start of inhalation. A capnogram without these normal attributes suggests an anomaly in the patient's cardiopulmonary system, a malfunction in the airway, a malfunction in the gas delivery system, or an error in the measurement system.[44]

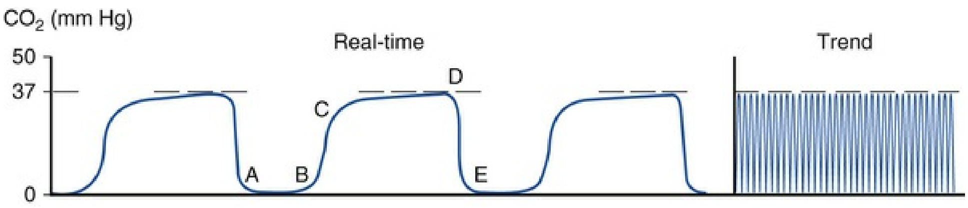

FIG. 46.5 Normal capnogram. (A-B) baseline during inspiration or dead space. (B-C) Expiratory upstroke (mix of dead space and alveolar gas). C-D: expiratory or alveolar plateau. D- end-tidal volume or $PETCO_2$. D-E: inspiratory downstroke. (Modified with permission from Zwerneman K. End-tidal carbon dioxide monitoring: a VITAL sign worth watching. Crit Care Nurs Clin N Am. 2006;18:217-225. Fig. 1.)

Clinical Applications

The role of P_{ETCO_2} monitoring has expanded in recent years to include prehospital and emergency department settings.[45-46] It can be used to verify tracheal intubation, detect complete airway obstruction, and monitor ventilation during sedation.[43,47-49] Capnometry and capnography are useful in verifying endotracheal tube position following intubation and serve as continuous monitors of endotracheal tube location. This is based on the observation that CO_2 is exhaled through the trachea and not from the esophagus, which allows differentiation between endotracheal and esophageal intubation.[50-51] Confirmation of endotracheal intubation with a calorimetric detector is highly accurate in pediatric patients and is more sensitive and specific when compared with pulse oximetry and auscultation on physical examination.[50] Capnography can also be employed during transport of patients for early detection of endotracheal tube dislodgement, allowing for faster correction and avoidance of life-threatening consequences related to hypoxic arrest.[52] This is particularly significant in the pediatric population where the distance between the vocal cords and carina is small.

P_{ETCO_2} monitoring can also be helpful in monitoring the respiratory status of patients placed on noninvasive positive pressure ventilation or during procedural sedation where a nonintubated patient's respiratory efforts are difficult to visualize.[53-54] Capnography may detect alveolar hypoventilation, earlier than pulse oximetry in patients receiving moderate sedation.

Finally, P_{ETCO_2} monitoring is becoming a routine monitoring parameter during cardiopulmonary resuscitation (CPR).[45,54] Of all prehospital vital signs, P_{ETCO_2} has been found to be the most predictive and consistent for mortality.[55] Recent Advanced Cardiac Life Support (ACLS) guidelines recommend using capnography to monitor the effectiveness of chest compressions during CPR.[56] A sudden decrease in P_{ETCO_2} is seen with loss of pulmonary blood flow in cardiac arrest. Increasing P_{ETCO_2} values generated during CPR are associated with chest compression depth and ventilation rate,[57] and an acute rise in P_{ETCO_2} exceeding 10 mm Hg is seen with return of spontaneous circulation.[58] Patients with ROSC after CPR have statistically higher levels of P_{ETCO_2}, suggesting better lung perfusion and cardiac output.[59] Current guidelines suggest achieving a threshold of 10 to 15 mm Hg to ensure adequate delivery of chest compressions, although an average P_{ETCO_2} level of 25 mm Hg was found in patients with ROSC in a recent systematic review and meta-analysis.[59-61] Ongoing studies will further elucidate P_{ETCO_2} goals and may be used to predict outcomes in the resuscitation setting.

Operating Principles of Capnometry

Sampling of exhaled CO_2 can be at the patient-ventilator interface (mainstream), diverted to a monitor (sidestream), or an intermediate connection.[49] In the most common sampling method, gas is diverted from the airway and aspirated through a tube (sidestream) to the CO_2 monitor. A low dead space sidestream CO_2 monitor is optimal for use in patients <10 kg in weight. An alternative to the diverting instrument is the nondiverting or “mainstream” capnometer in which a special flow-

through adapter and CO_2 monitor are placed in the patient's airway. The exhaled gas sample is exposed to various wavelengths of infrared light. The relative amount of light absorbed by the exhaled sample is compared with the amount of light absorbed by a sample that does not contain CO_2. By comparing the difference in absorption between the two samples, the capnometer determines the amount of CO_2 in the sample gas, which it then displays as the CO_2 concentration. CO_2 also can be measured semiquantitatively using a pH-sensitive indicator that changes from purple to yellow when exposed to CO_2.[47] The Easy Cap P_{ETCO_2} detector is placed between the endotracheal tube and resuscitation bag after intubation, and a color change from purple to yellow should be observed. Up to six breaths may be necessary to allow for washout of retained CO_2 in the event of esophageal intubation. A constant purple color indicates that the tube is not in the trachea or the presence of poor pulmonary perfusion while a tan color may indicate tracheal intubation with poor pulmonary perfusion or esophageal intubation with retained CO_2.

Clinical and Technical Issues

Both physiologic anomalies and technical factors can result in P_{ETCO_2} values that do not approximate Pa_{CO_2}. For P_{ETCO_2} to approximate Pa_{CO_2}, two assumptions must be met: (1) the lung units must empty synchronously with uniform time constants and (2) ventilation and perfusion must be well matched in the lung units. Additionally, technical variables can produce P_{ETCO_2} values that do not approximate Pa_{CO_2}. These include the design of the gas sampling system, distance the gas must be transported, and instrument's calibration methods.

Gas Sampling Issues

The gas sampling method used by a capnometer affects the accuracy of the capnogram and P_{ETCO_2} measurements. Relevant factors include the location of the ventilatory circuit from which the gas is sampled, the distance over which the gas is transported before analysis, and the sample flow rate of the instrument. With a nondiverting or mainstream device, the CO_2 monitor is placed on the airway, so there is no need to divert gas from the airway. This sampling configuration typically is available only in infrared capnometers because only infrared CO_2 monitors can be designed small enough to fit on the airway. A study comparing mainstream proximal end-tidal CO_2 to a novel method that sampled distal end-tidal CO_2 via a special double-lumen tube found that the distal end-tidal samples had the best correlation with Pa_{CO_2} and remained reliable even when severe lung disease was present.[62] Another sampling configuration is seen in the proximal-diverting device. A lightweight, low-profile airway adapter is placed in the patient's airway, and gas is sampled from the airway and transported to the sensor, which is placed near the patient but not in the airway itself. A third sampling configuration is found in the distal-diverting device, the classic “sidestream” capnometer. In a distal-diverting system, gas is sampled from the airway and transported to the CO_2 monitor, which is located in the display unit distal to the patient.

The accuracy of the capnogram, P_{ETCO_2} measurements, and displayed values depends on the sampling site (Fig. 46.6). In continuous gas flow circuits, sampling in or at the endotracheal tube results in the most accurate values because there is little contamination with fresh gas from the breathing circuit (point A). The Y-connector of the breathing circuit is the next best sampling site (point B). However, if the fresh gas flow is large compared with the expiratory flow rate of the patient (as may be the case in neonates and small children), the capnogram and P_{ETCO_2} values may be distorted as a result of dilution with the fresh gas flowing through the Y-connector. If gas is sampled "downstream" from the patient, the waveform and P_{ETCO_2} are increasingly diluted by fresh gas from the circuit (points C and D). If gas is sampled "upstream" from the patient in the fresh gas supply, none of the exhaled CO_2 is detected and the measured P_{ETCO_2} is zero (point E). Therefore the best sampling site is within the patient's endotracheal tube or at the tube connector, as far as possible from the Y-connector of the breathing circuit.[63]

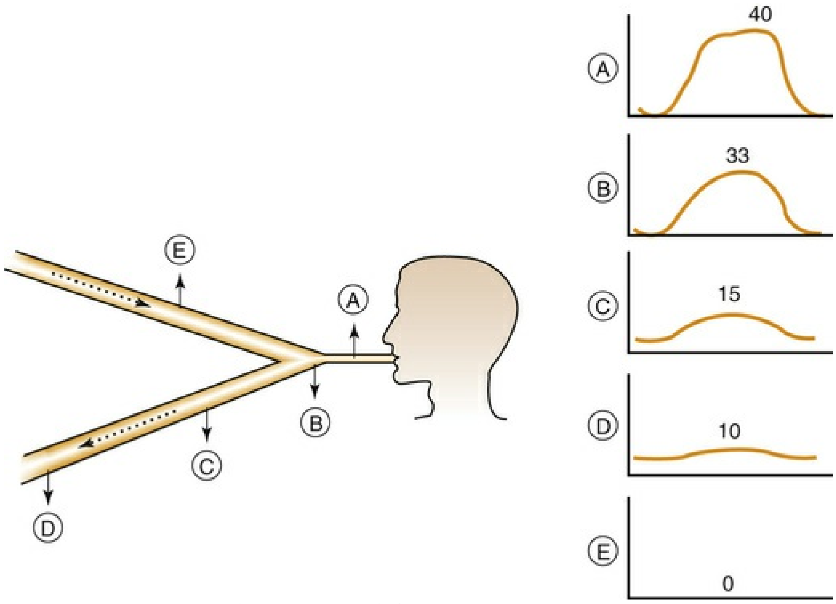

FIG. 46.6 Accuracy of end-tidal CO_2 measurements is highly dependent on obtaining good samples of expiratory gas from the patient. If sampled gas is contaminated with fresh gas from the breathing circuit, the measured values will not be accurate. The best samples are obtained from a site nearest to the source of CO_2, the patient (point A).

In breathing circuits with intermittent flow (demand-valve ventilators) and in larger children with large exhaled tidal volumes, the capnogram and P_{ETCO_2} values are usually unaffected by minor changes in sampling location. If the tidal volume is small (eg, as in infants and children) and the sample flow rate is large (ie, >150 mL/min), the capnogram and P_{ETCO_2} measurements may be significantly diluted by the entrainment of fresh gas. Using a capnometer system with a low sample flow rate, typically less than 75 mL/min, restores the waveform and P_{ETCO_2} readings to more accurate values.

Dead Space Ventilation

Dead space is the volume of gas in the airways and lung that participates in tidal breathing but does not participate in gas exchange. Obvious examples are the volume of the endotracheal tube and ventilator circuit (apparatus dead space) and the volume of the tracheal lumen and central airways (anatomic dead space). A less obvious, but still important, source of error in critically ill patients is alveolar or physiologic dead space. This dead space is attributable to lung units in which ventilation greatly exceeds perfusion. Gas exchange in these overventilated, relatively underperfused lung units is less efficient than normal.

The fraction of the tidal volume that is delivered to all dead spaces taken together can be calculated using the Bohr equation. A sample of mixed expired air collected over numerous breaths is analyzed for mixed P_{CO_2} (P_{ECO_2}). The total fraction of dead space per tidal volume is given by:

$$V_D/V_T = (PaCO_2 - PECO_2)/PaCO_2 \qquad \textbf{Eq. 46.4}$$

Physiologic dead space (V_D/V_T) can be determined from a variant of the Bohr equation:

$$V_D/V_T = (PaCO_2 - PETCO_2)/PaCO_2 \qquad \textbf{Eq. 46.5}$$

or

$$V_D/V_T = 1 - (PETCO_2/PaCO_2) \qquad \textbf{Eq. 46.6}$$

where P_{ETCO_2} is used in place of a sample of mixed expired air.

In many clinical situations, dead space ventilation is an appreciable fraction of tidal breathing, including severe respiratory dysfunction,[64] pulmonary hypoperfusion, pulmonary thromboembolism, and cardiac arrest (Box 46.1). In these conditions, the clinician using a capnometer may see a large arterial to end-tidal P_{CO_2} gradient (typically >10 mm Hg). This gradient can be used as an indicator of severity of disease, and P_{ETCO_2} can be used to evaluate trends rather than as a specific measure of alveolar P_{CO_2}.

Box 46.1

Clinical Conditions Associated with Abnormalities in P_{ETCO_2}

Increases in P_{ETCO_2}

Sudden
- Sudden increase in cardiac output
- Release of a tourniquet

Injection of sodium bicarbonate
Gradual
Hypoventilation
Increased metabolism (carbon dioxide production)

Decreases in $PETCO_2$

Sudden
Sudden hyperventilation
Sudden decrease in cardiac output
Massive pulmonary embolism
Air embolism
Ventilator disconnection
Ventilator circuit leakage
Obstruction of the endotracheal tube
Gradual
Hyperventilation
Decrease in metabolism (carbon dioxide production)
Decreased pulmonary perfusion
Absent $PETCO_2$
Esophageal intubation
Accidental extubation

Modified from Tobin M. Respiratory monitoring. JAMA. 1990;264:244-251.

Differential Diagnosis of Abnormal Capnograms

The capnogram probably is the single most reliable and effective monitor of pulmonary ventilation. The integrity and function of the patient's cardiopulmonary system and the breathing circuit both affect the capnogram, and malfunctions often can be detected by changes in the capnogram.[62,65]

Gradually Decreasing End-Tidal CO_2 Concentration

When the capnogram retains its normal morphology but there is a slow, progressive drop in $PETCO_2$ (Fig. 46.7), the possible causes include falling body temperature, slowly decreasing systemic or pulmonary perfusion, and hyperventilation. Sedation and neuromuscular blockade attenuate the normal body mechanisms for generating heat to preserve body temperature. As body temperature falls, the patient's rate of metabolism and CO_2 production also fall. If ventilation is controlled and kept constant as body temperature decreases, alveolar CO_2 concentration and arterial PCO_2 decrease. This decrease is reflected in the capnogram as a slow decrease in $PETCO_2$ over many minutes. Another cause of decreasing $PETCO_2$ is a fall in total body perfusion associated with blood loss or cardiovascular depression. As systemic and pulmonary perfusion decrease, alveolar dead space increases with a resultant fall in $PETCO_2$.

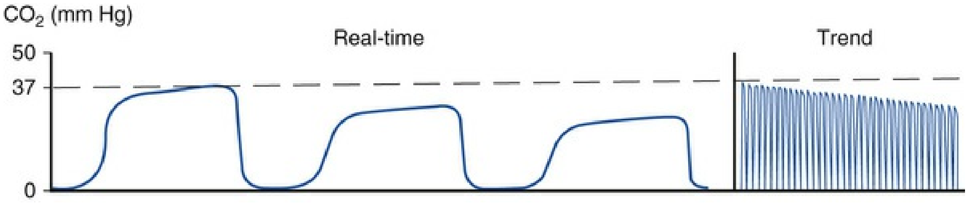

FIG. 46.7 Decreasing P_{ETCO_2} level. (Modified with permission from Zwerneman K. End-tidal carbon dioxide monitoring: a VITAL sign worth watching. Crit Care Nurs Clin N Am. 2006;18:217-225. Fig. 6.)

Sustained Low End-Tidal CO_2 Concentrations Without Plateaus

Occasionally, with no apparent malfunction in the breathing circuit or in the patient's cardiopulmonary status, the capnogram shows sustained low P_{ETCO_2} values without a good alveolar plateau (Fig. 46.8). In this situation, P_{ETCO_2} is not a good estimate of alveolar P_{CO_2}. The absence of a good alveolar plateau suggests that either full exhalation is not occurring before the beginning of the next breath or the patient's tidal volume is being diluted with fresh gas because of a small tidal volume, high aspirating sample rate, or high fresh gas dilution from the circuit. Several maneuvers are available to distinguish between these possibilities.

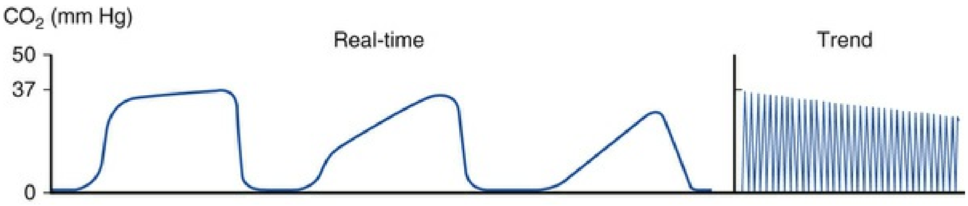

FIG. 46.8 Airway obstruction or obstruction in breathing circuit. (Modified with permission from Zwerneman K. End-tidal carbon dioxide monitoring: a VITAL sign worth watching. Crit Care Nurs Clin N Am. 2006;18:217-225. Fig. 7.)

Incomplete emptying of the lungs may be suggested by adventitial sounds such as wheezing or large airway rhonchi with compromise of small airway patency caused by bronchospasm or secretions. If rhonchi are present, tracheal suctioning often corrects the partial obstruction and restores full exhalation. Bronchospasm may be treated with a variety of bronchodilators. An endotracheal tube that is kinked or partially obstructed by secretions may prevent full exhalation. Passing a suction catheter down the endotracheal tube usually confirms or eliminates this possibility. Gently squeezing the child's chest to assist with a forced exhalation often produces a waveform in which the CO_2 concentration continues to rise toward an alveolar plateau. If the plateau is present, the “squeeze P_{ETCO_2}” value may be taken as a good estimate of alveolar CO_2 concentration.

When no signs of partial airway obstruction are present, another explanation for this type of capnographic waveform should be considered. In infants and other patients who have small tidal volumes, the aspirating sample rate may exceed the expiratory flow rate near the end of exhalation. When this occurs, the aspirating

sample is diluted with fresh gas from the breathing circuit, resulting in a drop-off of the plateau and a fall in P_{ETCO_2} as a result of dilution. Reducing the flow rate of fresh gas or moving the sampling site closer to the endotracheal tube connector usually corrects the problem. In very small newborns, a sample rate of 100 to 250 mL per minute may be too high to result in good plateaus despite instituting the preceding corrective measures. Then either a capnographic system having a very low sampling rate (50 mL/min) can be used or the capnogram can be used as a gross monitor of the integrity of the ventilatory circuit and trends in cardiopulmonary function rather than as an accurate estimate of alveolar ventilation.

Sustained Low End-Tidal CO_2 Concentration With Good Plateaus

In some circumstances, the capnogram demonstrates a low P_{ETCO_2} with a widened (a-et) ΔP_{CO_2} and preservation of a good alveolar plateau. This discrepancy may indicate that the capnograph is malfunctioning or miscalibrated. The clinician can evaluate this possibility by sampling his or her own exhaled CO_2 and verifying that the P_{ETCO_2} concentration is between 5% and 6% (equivalent to approximately 38 to 46 mm Hg). If the instrument is functioning properly and is well calibrated, a wide (a-et) ΔP_{CO_2} is an indication of excessive dead space ventilation in the patient.

Exponential Decrease in End-Tidal CO_2

An exponential drop in P_{ETCO_2} that occurs within a short time (eg, a dozen or so breaths) almost always signals a sudden and probably catastrophic event in the patient's cardiopulmonary system (see Fig. 46.7). The basis for this capnogram is a sudden and dramatic increase in alveolar dead space ventilation. Possible causes include sudden hypovolemia, circulatory arrest with continued pulmonary ventilation, and pulmonary embolus with thrombus or air. Only after ruling out these catastrophic events and determining that the patient is hemodynamically stable should more mundane explanations for the exponential decay in P_{ETCO_2} be considered. The most common noncatastrophic cause is an accidental increase in ventilation attributable to an incorrect ventilator adjustment, resulting in a gradual decrease in P_{ETCO_2}. However, it is important to note that even doubling the alveolar ventilation decreases the P_{ETCO_2} to only half of the preadjustment value, not to the near-zero values that may accompany catastrophic cardiopulmonary events.

Gradual Increase in Both Baseline and End-Tidal CO_2

A gradual rise in both baseline and P_{ETCO_2} value indicates that previously exhaled CO_2 is being rebreathed from the circuit (Fig. 46.9). In this situation, the inspiratory portion of the capnogram fails to reach the zero baseline, and there may actually be a premature rise in CO_2 concentration during the inspiratory phase of ventilation. P_{ETCO_2} usually increases until a new equilibrium alveolar CO_2 concentration is reached, when excretion once again equals production.

(B) Rising baseline. (Modified with permission from Zwerneman K. End-tidal carbon dioxide monitoring: a VITAL sign worth watching. Crit Care Nurs Clin N Am. 2006;18:217-225. Fig. 4.)

FIG. 46.9

Transcutaneous Monitoring

Transcutaneous measurements reflect both gas exchange and skin perfusion. The development of portable, miniaturized electrodes led to the use of this technology to continuously measure both oxygen and CO_2 tension transcutaneously. In this technique, a probe composed of a heater, an electrode, and a thermistor is applied to the patient's skin. The skin is warmed and softened to improve diffusion and permeability. This step also causes capillaries to dilate, resulting in better approximation of arterial oxygen values. This technology works under the assumption that transcutaneous values reflect those from the arterial circulation. Heating the skin allows more rapid diffusion of both oxygen and carbon dioxide from the subcutaneous tissues to the surface of the electrode. However, the heating affects both tissue and blood by decreasing oxygen solubility, shifting the oxyhemoglobin dissociation curve to the right, and dilating local arterioles. Temperatures of 44°C to 45°C increase diffusion and prevent vasoconstriction in the local area of the skin.[66]

Oxygen Monitoring

Transcutaneous Clarke electrodes measure oxygen tension in a local segment of the heated skin. Because skin is the organ most responsive to adrenomedullary induced

vasoconstriction, local oxygen tension may not be the same in all skin segments or other tissues. In essence, transcutaneous oxygen tension ($TcPO_2$) is only an indirect reflection of arterial oxygen tension; it is more directly related to local tissue perfusion and oxygenation.

This technology has several limitations and disadvantages that limit the use of transcutaneous monitoring to the newborn population. Skin thickness increases with age, making transcutaneous measurements less predictable. Electrode placement must be changed every 4 to 6 hours to prevent thermal injury to the site of measurement or when readings become unstable. A thermal neutral environment to limit peripheral vasoconstriction increases the correlation between transcutaneous and arterial tensions. Finally, the electrode membranes must be calibrated before each use and each change of measurement site, and comparison with arterial blood gases is necessary. However, displaying $TcPO_2$ has been shown to result in less time spent hyperoxemic and less time spent hypoxemic than displaying the SpO_2, which may be particularly useful in infants.[67] Because of these limitations and the ease of application of pulse oximetry and P_{ETCO_2} monitoring, transcutaneous oxygen monitoring has nearly been replaced by other monitoring methods.

Carbon Dioxide Monitoring

Transcutaneous CO_2 tension using a Stowe-Severinghaus electrode has been widely used in the neonatal population to approximate Pa_{CO_2}. Transcutaneous CO_2 values parallel but consistently overestimate Pa_{CO_2} values in hemodynamically stable neonates and adults.[68] The difference in arterial and transcutaneous values reflects accumulation of CO_2 in the tissues as a result of inadequate perfusion. Transcutaneous monitoring of CO_2 more closely approximates arterial CO_2 tension in infants and children who are experiencing respiratory failure than does P_{ETCO_2}.[69-71] This technology is also useful in settings where nonconventional forms of ventilation (high-frequency ventilation) preclude the use of end-tidal monitoring.

Conclusion

Noninvasive monitors, such as pulse oximetry and capnometry, are standards of care in the pediatric critical care environment. It is therefore important to understand key clinical and technical issues that determine how these instruments can be used most effectively. These noninvasive technologies provide early warning of potential catastrophic events and facilitate early intervention, with potential for better outcomes. Concerns for complications related to invasive monitors will continue to drive the search for newer and better devices for noninvasive physiologic monitoring. Promising recent advances have been made in the technology of pulse oximeters, allowing measurements of all types of hemoglobin, including dyshemoglobins and total hemoglobin, with less artifact resulting from patient movement, which is a vital consideration in the PICU patient population. However, with all of the technologic advances, we must remember the importance of basic vital sign monitoring and clinical observation, such as heart rate, respiratory rate, temperature, and fluid balance.

CHAPTER 47

Overview of Breathing Failure

Katherine V. Biagas, Robert K. Kanter †, Navyn Naran, Bradley P. Fuhrman

PEARLS

- Three pathways to breathing failure are (1) impaired neural control, (2) failure of the muscles of breathing, and (3) dysfunction of the mechanics of breathing.
- Though diverse stimuli drive respiratory cycling and effort, all must be processed by the brain to affect respiratory muscles. For this reason, brain death entails loss of all respiratory effort.
- Volitional control of breathing is supratentorial and may dominate automatic control in the awake state, but it may be lost in brain injury with or without loss of automatic control.
- Automatic control of breathing is integrated in the medulla and involves numerous separate brain stem regions, which are so widely dispersed that some evidence of respiratory drive may persist even after near-total loss of brain function.
- Muscles of breathing include the diaphragm, intercostals, and accessory muscles. The diaphragm works like a piston to expand the thorax and displace abdominal organs caudad. Intercostal muscles participate in both inspiration and expiration. The thoracic accessory muscles (scalenes, sternocleidomastoids, pectoralis minor, and erector spinae) all elevate the ribs and facilitate inspiration. The abdominal muscles (rectus abdominis, transverse abdominis, and the obliques) facilitate expiration.
- The respiratory muscles can fail from overwork (as might occur in asthma) or from inadequate supply of blood, oxygen, or nutrients (as might occur in shock or sepsis, even when there is no evidence of lung disease).
- Dysfunction of the mechanics of breathing can contribute significantly to respiratory muscle workload, predominantly through imposition of inefficiencies. Assisted ventilation can (1) prevent breathing failure from progressing to respiratory arrest, (2) improve gas exchange, and (3) reduce metabolic expenditure for muscle work in the patient with limited reserve.

Respiration involves movement of air (breathing), diffusion of gases between alveolus and pulmonary circulation, circulation of blood between tissue and lung, and tissue energy metabolism. This chapter provides an overview of spontaneous breathing and breathing gone awry and sets the stage for later chapters on respiratory disorders. The term "breathing failure" is used here to limit consideration to mechanical failure of the respiratory pump that drives air movement. Breathing failure is arguably the most common cause of arrest in infants and children.

Physiology of Breathing

Diaphragm

The diaphragm arises from the embryologic pleuroperitoneal fold. Myoblasts migrate from cervical somites to the pleuroperitoneal fold, where they arrange themselves into a sheet on a mesenchymal substrate that separates the peritoneum from the abdomen. Once fully formed, the diaphragm originates from bilateral tendinous crura attached to the spinal column and inserts as a costal tendon attached to the chest wall between the sixth and twelfth ribs. The dome of the diaphragm remains largely tendinous. This configuration, a circular attachment to the thoracic wall, vertical muscle orientation adjacent to the thorax, and attachment to a flattened central tendinous dome (Fig. 47.1), works like a piston during breathing to enlarge the thorax and displace abdominal contents downward.

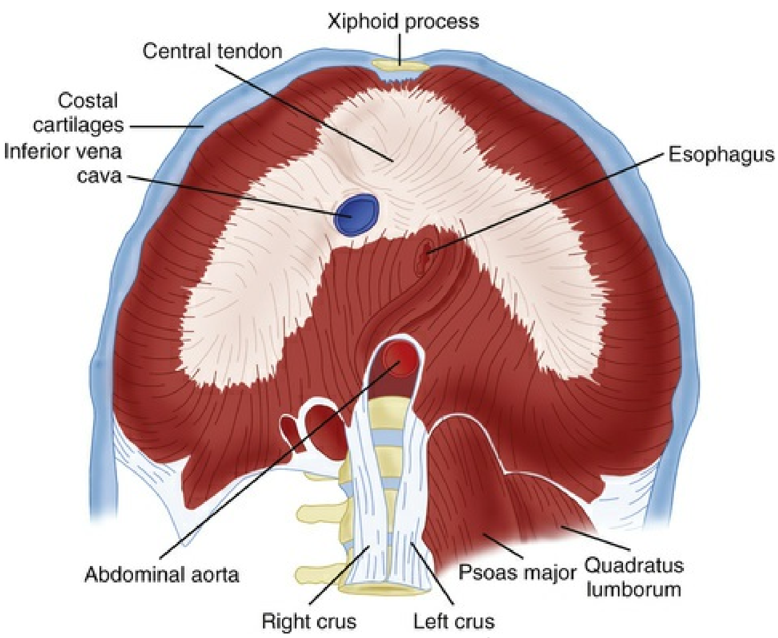

FIG. 47.1 The diaphragm is attached circumferentially to the thoracic wall. Its muscular portion extends onto the dome, where it is tendinous and flattened. When the muscle contracts, the dome descends like a piston, enlarging the thorax and displacing abdominal contents downward.

Approximately 50% of the diaphragm consists of type I fast-twitch muscle fibers, which have high endurance and are resistant to fatigue. The remainder of the

diaphragm is made up of type IIA and type IIB fibers, which have different properties.[1] Type IIA fibers are important in achieving high levels of minute ventilation quickly, have good endurance, and can contract rapidly, but they are unable to sustain long-term power output. Type IIB fibers cannot sustain their force of contraction because they possess lower oxidative capacity and are more susceptible to fatigue. The greater the force of contraction required, the more motor units of the diaphragm are recruited. There appears to be little difference between the activity of costal muscles and crural muscles, either during normal breathing or in response to hypoxia and hypercapnia.

When a patient lies supine, the diaphragm rests against the inner surface of the rib cage. When the diaphragm contracts and its muscle fibers shorten, the whole diaphragm moves down, lowering pleural pressure and increasing intra-abdominal pressure. The increase in intraabdominal pressure generated by descent of the diaphragm acts as a caval pump to enhance cardiac filling.[2] Because of its alignment against the lower ribs (zone of apposition), descent of the diaphragm also expands the caudal portion of the rib cage.

The muscle of the diaphragm extends from the costal insertion to the dome of the diaphragm. When the diaphragm is “high,” it is loaded for greater force of contraction. When it is “low” or “flat,” it is unloaded and mechanically disadvantaged.

The diaphragm is the major inspiratory muscle of the neonate. It increases in thickness with age (as its muscle mass increases). It also becomes appositional to a longer segment of chest wall with growth, enhancing its effectiveness as an inspiratory piston.[3] In the neonate, the muscular diaphragm has a greater angle from the vertical than that of the adult, which reduces its effectiveness as an air pump (Fig. 47.2). This angle approaches zero with growth, increasing the diaphragm's effectiveness with advancing age. The importance of this angle as an impediment to diaphragmatic effectiveness becomes exaggerated at total lung capacity, with air trapping, and when the abdomen is distended, all of which flatten and unload the diaphragmatic muscle (Fig. 47.3).

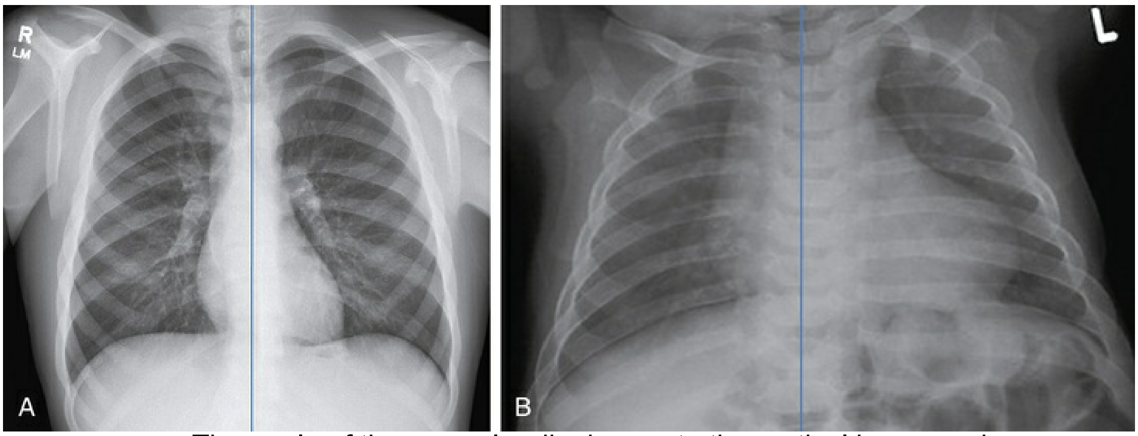

FIG. 47.2 The angle of the muscular diaphragm to the vertical is narrow in the older child (A) and adult than it is in the infant (B). This more horizontal traction on the dome may be disadvantageous when the muscle of the infant diaphragm contracts. (Courtesy Women & Children's Hospital of Buffalo, NY.)

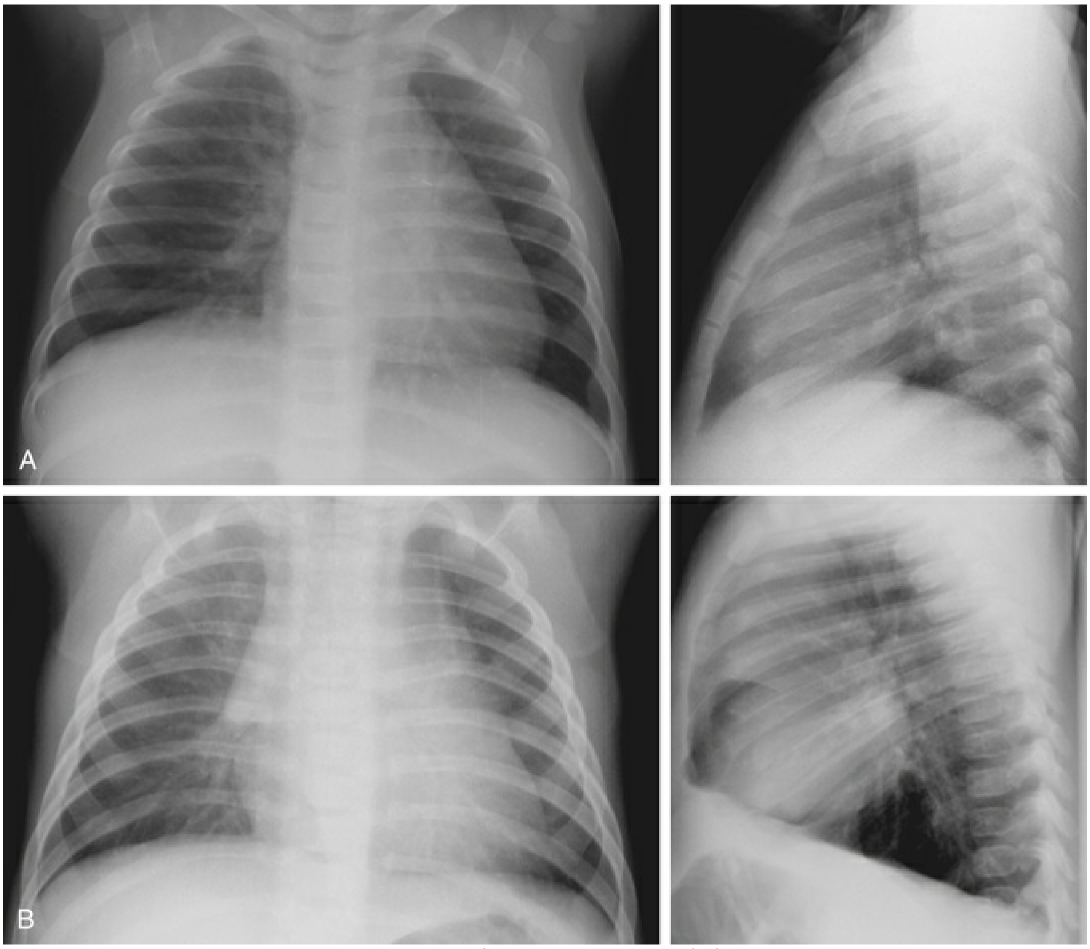

FIG. 47.3 The normal position of the diaphragm (A) allows it to stretch or "load" during expiration. In inspiration, its muscular attachment to the thorax pulls it vertically downward. Air trapping (B), abdominal distension, or other disorders that cause flattening of the diaphragm interfere with "loading" and with the direction of contraction. (Courtesy Women & Children's Hospital of Buffalo, NY.)

Intercostal Muscles

The rib cage is fixed to the spine and sternum. The spine maintains a relatively fixed separation between adjacent ribs. Vertical mobility of the sternum allows lift and descent of the anterior rib cage. Thoracic volume is modified during breathing primarily by changing the angle of the anterior ribs to the horizontal. At rest, the ribs slope caudad from their spinal attachments. The rib cage tilts upward during inspiration. The intercostal muscles form three functional sheets. The outermost (external) sheet and the parasternal sheet act to displace the ribs cephalad as they shorten. This increases both the anteroposterior and lateral dimensions of the thorax. There is also a deep (internal) layer of intercostal muscle at right angles to the external sheet that acts to displace the ribs caudad when it contracts. Thus the intercostal muscles play both inspiratory and expiratory roles in breathing by reshaping the thorax.

Accessory Muscles of Respiration

Though quiet expiration is largely passive, resulting mostly from inward elastic recoil of the lung, active expiration may be assisted by contraction of abdominal muscles (rectus abdominis, transverse abdominis, and the obliques). During quiet breathing, abdominal muscle tone elevates the diaphragm during expiration, increasing the zone of apposition and loading the diaphragm for greater inspiratory contractile efficiency.

Accessory muscles of inspiration include the scalenes, sternocleidomastoids, pectoralis minor, and erector spinae, all of which elevate the ribs during contraction. During quiet breathing, accessory muscles play a minor role, but during respiratory exertion, they may play a major role and act to unload and unburden the diaphragm and intercostals. Even profoundly neurologically impaired children, who exhibit little volitional activity, can use accessory muscles of breathing when distressed. Children with dysfunction of the primary muscles of respiration may rely on their accessory muscles even at rest.

Controls of Breathing

Powerful neural regulation of breathing maintains a constant supply of oxygen to the tissues, despite wide variations of metabolic rate and respiratory system disorders, until an advanced stage of respiratory failure is reached. Sick or injured patients usually hyperventilate in compensation for stressful disorders. Stressed patients with irregular breathing or inappropriately comfortable effort to breathe probably have a severely depressed respiratory drive warranting ventilator support. Derangements of respiratory controls may be the primary cause of acute respiratory failure or one of multiple causes in a critically ill or injured patient. In other patients, disorders of respiratory regulation prolong dependence on mechanical ventilation. Disorders of respiratory controls may be difficult to distinguish from, and may combine with, muscle failure and altered respiratory mechanics.

Normal Regulation of Breathing

Rhythmic discharges whose timing corresponds to inspiratory and expiratory phases are generated in the pre-Bötzinger complex of the ventrolateral medulla oblongata.[4,5] During resting breathing, inspiratory efferent activity stimulates diaphragm flattening, as well as increased pharyngeal muscle tone and vocal cord abduction essential to keep the upper airway patent during inspiratory airflow. When inspiratory muscles relax, resting expiration is passive, driven by elastic recoil of the lung and chest wall.

The respiratory rate, inspiratory time, and motor intensity are modified by a variety of rostral neural, chemical, and mechanical stimuli (Fig. 47.4). With high-intensity stimulation, accessory muscles of breathing are activated, including intercostals and neck muscles. Nasal flaring occurs. Stimulated breathing also may include end-inspiratory vocal cord closure that prolongs lung inflation with little energy expenditure, clinically evident as a grunting vocalization when the vocal cords open at the beginning of expiration. In highly stimulated breathing, abdominal muscles contract to force expiratory airflow. Other normal respiratory control

behaviors include periodic deep inspirations, sneezing, and coughing to maintain expansion of basal lung areas and clear secretions from the respiratory tract. Breathing is normally coordinated with swallowing, vocalizing, and airway protective reflexes to prevent aspiration.[6] Pharyngeal muscle tone is also adjusted with neck flexion and extension to maintain airway patency.

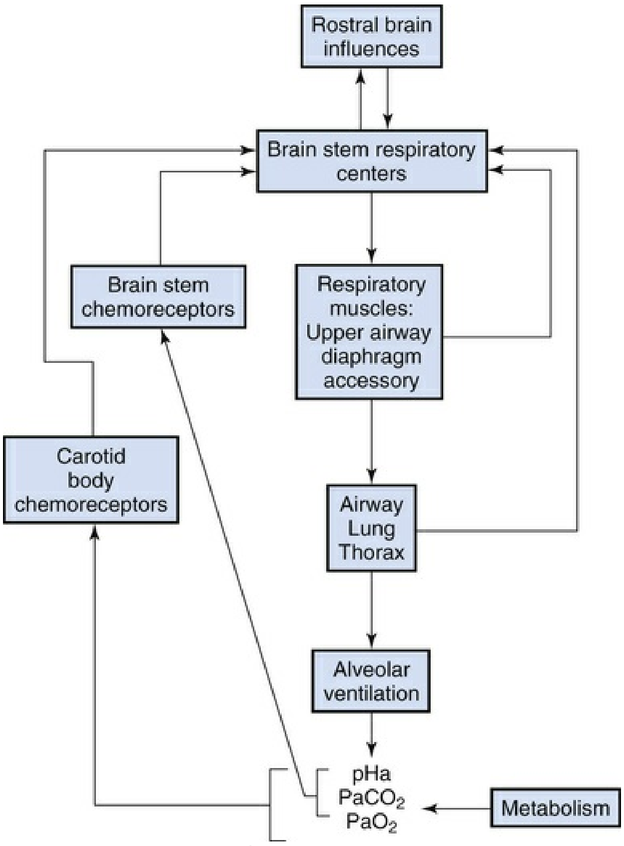

FIG. 47.4 Elements of the respiratory control system.

Hypoxemia is a powerful stimulus to ventilation mediated by sensory input originating in the carotid body chemoreceptor. Peripheral chemoreceptor activity and ventilation increase slightly as Pao_2 falls below 500 mm Hg. Ventilation rises steeply as Pao_2 falls below 50 mm Hg (Fig. 47.5A). Low arterial oxygen tension, rather than low oxygen content, is the ventilatory stimulus. Little carotid body response results from profound anemia. Hydrogen ion concentration and carbon dioxide tension independently activate chemoreceptors in the carotid body and brain stem (Fig. 47.5B). The simultaneous presence of hypoxia augments the hypercapnic ventilatory response (Fig. 47.5C).

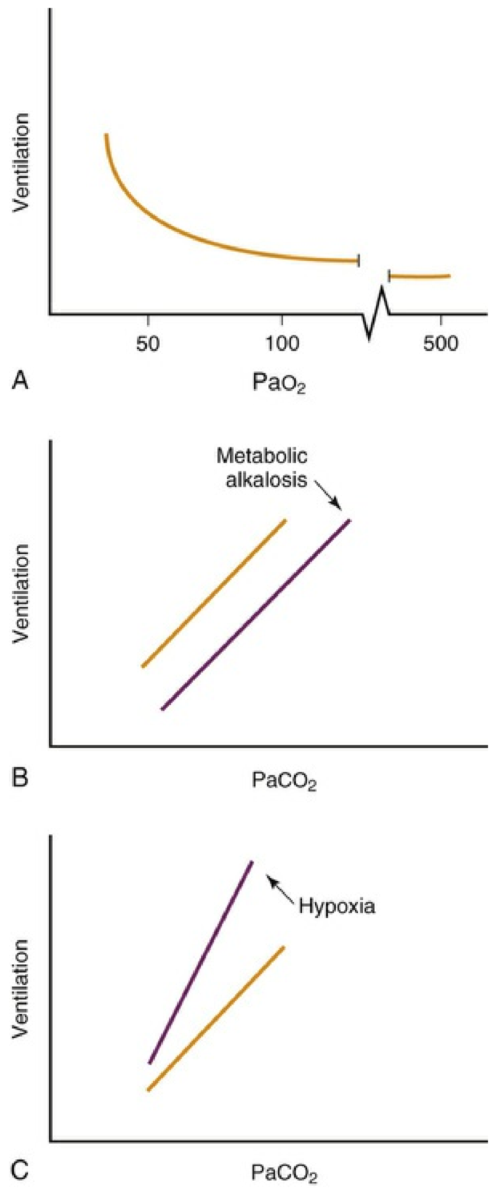

FIG. 47.5 Chemoreceptor activity, as measured by minute ventilation, varies as a function of PaO_2 (A), $PaCO_2$ (B) (superimposed metabolic alkalosis inhibits breathing), and $PaCO_2$ (C) (superimposed hypoxia further stimulates breathing).

Mechanical loads on breathing influence respiratory efforts immediately, independent of chemical stimuli. Sensors for load-compensating reflexes are located in respiratory muscles and the chest wall. Reduction in lung volume is also detected by pulmonary stretch receptors. Afferent signals pertaining to loaded breathing travel via the spinal cord, vagus nerves, and perhaps the phrenic nerves. Both conscious and reflex responses are involved in compensatory increases of effort, including the recruitment of accessory muscles in response to increased respiratory resistance or to a decrease in compliance. Stimulation to breathe is further augmented by hypercapnia or hypoxemia when loaded breathing reduces ventilation. Respiratory compensation for mechanical loads accounts for the increased respiratory effort in patients who maintain normal blood gas tension or hypocapnia despite abnormal respiratory mechanics. Dyspnea and anxiety

exacerbate the tendency to hyperventilate even without a chemical ventilatory stimulus.

Sleep modifies breathing, and compensation for respiratory illness is most likely to fail during sleep.[7] In some persons ventilatory responses to hypercapnia and hypoxia diminish during sleep. Sleep-induced reduction in upper airway tone and cough reflexes worsens the risk of obstruction and aspiration. In infants, whose thorax is compliant, awake lung volume is maintained by thoracic muscle tone and breathing at sufficiently high frequencies that expiration seldom reaches the passive resting lung volume. During sleep, inspiratory muscle tone diminishes and respiratory rate decreases, with resulting reduction in infants' expiratory lung volume. Infants' compensation for mechanical loads is compromised during the rapid eye movement stage of sleep more than during quiet sleep.

Breathing Failure

When challenged, muscle tension can be augmented by increasing either the frequency of firing or number of motor units being fired. At low muscle tension, the *number* of motor units participating in contraction may be increased before frequency is raised. Recruitment is used to increase work. To achieve an even greater increase in force, the *frequency* of firing of individual motor units may be raised, such that while the number of motor units is held constant the *work* of each motor unit is increased.

Working skeletal muscles rely on a continuous supply of oxygenated blood. Diaphragmatic function can be impaired if blood flow or oxygenation is reduced. Diaphragmatic muscle cannot operate at optimal length (force-length relationship) to generate the appropriate contraction (force-velocity relationship) if energy demand outstrips energy supply. The combination of suboptimal force-length and force velocity relationships causes rapid, shallow breathing, largely from dysfunction of type IIB fast-twitch glycolic fibers.

Respiratory muscle fatigue develops during exhaustive exercise. Prolonged malnutrition has also been shown to affect the diaphragm's muscle structure and impair its ability to generate force. On the other hand, it has been shown that respiratory muscle training can lessen the development of respiratory muscle fatigue.[8] Training of the diaphragm can increase capillary density, myoglobin content, mitochondrial enzyme concentration, and the concentration of glycogen, but persistent mechanical ventilation (particularly during deep sedation or paralysis) decreases muscle strength by allowing disuse muscle atrophy.

In acute illness, breathing fails if respiratory muscle demand for blood flow, metabolic substrate, and oxygen delivery outstrips supply, just as it does in exhaustive exercise.[9] The point at which this occurs is influenced by many factors, including the energy cost of breathing, duration of contraction per breath, velocity of contraction, operational length of muscle fibers, energy supply, efficiency of muscles, and state of muscle training.[10] Breathing failure, if untreated, may cause respiratory arrest and death.

Final Common Pathways to Breathing Failure

Several discrete mechanisms may cause breathing failure (Table 47.1). Each of these

final common pathways may be triggered or compounded by other discrete adversities, and independent pathways of breathing failure may converge to cause respiratory arrest (or need for mechanical support of breathing).

TABLE 47.1

Failure of Breathing

Mechanism	Examples
Failure of neural control	Uncal herniation, central hypoventilation
Failure of muscles of breathing	Insufficient muscle blood flow, hypoxemia
Failure of mechanics of breathing	Flail chest, diaphragmatic paralysis

Failure of Respiratory Controls

Disorders of respiratory controls may present with impaired respiratory cycle generation (central apnea), deficient responses to respiratory stimuli (hypoventilation during stress and failure to arouse from sleep hypoxia), or inadequate motor control of the vocal cords or pharynx (causing stridor or stertor). These patterns of regulatory dysfunction may occur individually or in combination. Pulmonary hypertension as a result of recurrent hypoxia, or aspiration pneumonia associated with impaired airway protective reflexes, may complicate the clinical situation.

Acute Failure

Patients with a critical illness or injury generally hyperventilate. When a stressed patient fails to hyperventilate, depressed respiratory controls and impending respiratory failure should be suspected.

Moderate brain injuries are typically associated with hyperventilation, whether the injury is traumatic, infectious, or hypoxic-ischemic. The hypermetabolic state, lung pathology, and loss of inhibitory cortical influences probably combine to augment ventilation. Even when the brain-injured patient does hyperventilate, airway protective reflexes are usually impaired, seizures may ensue, and subtle progression of the brain lesion may lead to hypoventilation. Resulting hypoxia exacerbates the brain injury.

Seizures impair breathing in various ways. Apnea or slowing of respiratory rate, impairment of upper airway protective reflexes, and poor inspiratory effort are common. The clinician must have a high index of suspicion to recognize occult seizures in infants. The seizure-induced respiratory depression may be difficult to distinguish from the brain pathology that caused the seizure, as well as the respiratory-depressing effects of anticonvulsant medications.

Respiratory depression by analgesic, sedative, anticonvulsant, and anesthetic agents is common. Relative effects on upper airway patency and hypoxic, hypercapnic, and loading responses may be dissociated. Concern regarding respiratory depression does not warrant withholding analgesia. Rather, monitoring should be appropriate. In fact, the patient suffering pain may breathe shallowly, exacerbating hypoxia. Sedatives and analgesics that are rapidly cleared after a single dose may have a more prolonged duration of action when given repeatedly or continuously. Clearance rates for medications may vary with systemic disease, immaturity, or genetic factors. Sedation and analgesic-induced respiratory

depression may unnecessarily prolong the need for mechanical ventilation.

Opioid-induced respiratory depression can be reversed with naloxone. In patients with cardiovascular compromise (eg, those who have had cardiac surgery), naloxone should be avoided in the immediate postoperative period because the stress of abruptly eliminating opioid anesthesia is hazardous. In the patient with multiple chronic drug ingestions, naloxone may induce vomiting without improving airway protective reflexes, predisposing the patient to aspiration. The benzodiazepine antagonist flumazenil reduces the respiratory depression that results from taking benzodiazepines, but little pediatric experience with this agent has been reported. Flumazenil lowers the threshold for seizures and may cause a more hazardous condition than the initial respiratory depression. The duration of action of antagonists may be shorter than the agent that is depressing breathing. Close monitoring of the patient is essential, and repeated doses of antagonists may be necessary. In other cases of drug-induced respiratory depression, mechanical ventilation provides greater safety than do pharmacologic antagonists. This is the case with multifactorial central depression or in severely ill patients.

Other medications may depress breathing without alteration of consciousness. For example, prostaglandin E_1, which is given to maintain patency of the ductus arteriosus in infants with congenital heart disease, is frequently associated with respiratory depression. The respiratory inhibitory action of metabolic alkalosis may contribute to prolonged dependence on mechanical ventilation in children receiving chronic doses of diuretic agents. When metabolic alkalosis accompanies prolonged recovery from respiratory failure, correction of the alkalosis with potassium chloride and occasionally acetazolamide may promote ventilator weaning.

In the advanced stage of respiratory failure, the vigorous respiratory effort of the dyspneic patient may become counterproductive. Agitation increases oxygen consumption, and forced respiratory efforts may cause dynamic obstruction of airways. Dynamic airway obstruction in the dyspneic child may account for rapid progression of respiratory failure in some cases.

As the severely dyspneic patient decompensates, exhausted efforts may rapidly give way to periodic breathing and apnea. While this phenomenon is commonly observed in infants with lower respiratory infections[11] and pertussis,[12] observations in adults with near-fatal asthma reveal a similar tendency for respiratory arrest to precede cardiovascular collapse.[13] The mechanism of this terminal respiratory depression with severely loaded breathing is not well understood, but it appears to occur in some patients before the development of life-threatening hypoxia and hypercapnia.

Chronic Failure

Congenital or long-standing acquired disorders of the central nervous system may impair respiratory centers, leading to respiratory failure. Acute respiratory insufficiency may accompany progression of a central lesion. A static regulatory impairment may be revealed by failure to compensate for acute systemic illness.

Structural Brain Lesions.

Recognition of structural brain lesions as the cause of impaired respiratory regulation is important because some of the lesions are correctable. Congenital structural neurologic malformations may manifest as apnea or profound

hypoventilation at birth or may be recognized later. In particular, patients with Chiari malformations often have central and obstructive sleep apnea.[14] Surgical decompression may be associated with improvement even when performed in adults.[15] Acquired lesions such as posterior fossa tumors may interfere with respiratory regulation before or after surgical resection.

Nonstructural Congenital Disorders.

Some genetic conditions are associated with derangements in regulation of breathing. Children with congenital central hypoventilation syndrome[16] have characteristic mutations in the *PHOX2B* gene. These patients may first come to medical attention because of growth failure, neurodevelopmental disabilities, or cor pulmonale. Abnormalities include autonomic dysfunction and cardiovascular instability, occasional association with Hirschsprung disease, tumors of neural crest origin, as well as impaired controls of breathing. The syndrome may be recognized in the newborn period, later in childhood, and rarely in adults. Sleep hypoventilation predominates in persons with congenital central hypoventilation syndrome, although some patients also experience respiratory insufficiency while awake. The disorder is often fatal without mechanical ventilation. Early mechanical ventilation may reduce the sequelae and improve long-term neurodevelopmental outcome.

Prader-Willi syndrome is a multigenic disorder initially presenting with hypotonia and then with progressive obesity, growth failure, neurodevelopmental disabilities, reduced ventilatory response to hypoxia and hypercapnia, sleep hypoventilation, and apnea.[17]

Rett syndrome is an X-linked disorder affecting development, behavior, autonomic and respiratory regulation, and seizures. Occurring only in girls, most cases involve spontaneous mutations, although occasionally other family members are affected. Abnormalities are often present in the *MECP2* gene, although some patients with characteristic clinical features have other genetic findings. Multiple phenotypes exist in regard to the respiratory control disorder, with hyperventilation, hypoventilation while awake or asleep, and apneustic breathing.[18]

Many other genetic syndromes with severe neurologic manifestations have impaired upper airway motor function, respiratory cycle timing, and respiratory effort nonspecifically associated with their brain disorder. Nongenetic congenital disorders may impair respiratory controls. For example, children with cerebral palsy occasionally have neurologic deficits of pharyngeal tone, although the central drive to breathe is usually intact.

Nonstructural Acquired Chronic Disorders.

Some patients with severe chronic respiratory disease have blunted ventilatory responses to hypoxia, hypercapnia, or respiratory mechanical loads. A concern regarding supplemental oxygen is sometimes raised in the care of patients with acute exacerbations of chronic respiratory disease. It is sometimes argued that administration of supplemental oxygen causes respiratory failure in patients with chronic CO_2 insensitivity who might depend on hypoxic drive to breathe. However, the adverse effects of hypoxia are a greater concern. Because the hypoxic drive to breathe only increases substantially at oxygen tension below 50 mm Hg (Fig. 47.5A), it is virtually impossible to maintain stable respiratory stimulation with mild and

"safe" hypoxia without risking episodic life-threatening hypoxia. If a patient is so poorly compensated that removal of hypoxic drive results in hypoventilation, then mechanical ventilation may be the safest management strategy, unless end-of-life plans specifically exclude mechanical ventilation.

Obesity causes hypoventilation by a complex interaction of factors including mechanical loads on the respiratory system, reduction of lung volume, upper airway obstruction, and impaired respiratory regulation. In obese patients, weight loss often improves hypoventilation.[19]

Apparently healthy preterm infants may have postanesthetic apnea until the age of 60 weeks' postconceptional age.[20,21] Apneic events occurred within 2 hours of surgery in 72% of patients, but in the remainder, respiratory irregularity began as late as 12 hours postoperatively. Both obstructive and central mechanisms of apnea were observed. Continuous monitoring for at least 12 hours after anesthesia is warranted when surgery is required for infants born prematurely who are still younger than 60 weeks' postconceptional age.

Sleep hypoventilation tends to occur in adults with hypothyroidism and diabetes mellitus.[22] Little information is available regarding the pediatric patient or the specific role of the endocrine disorder versus obesity.

Recognizing Depressed Respiratory Drive.

Respiratory neural output is not routinely directly measured in the clinical setting. Interpreting ventilation as a measure of the intensity of drive to breathe is confounded by dependence of ventilation on the multiple factors of muscle strength, respiratory system mechanics, as well as respiratory neural motor output. Nevertheless, the stressed patient who appears inappropriately comfortable, with little accessory muscle activity, or with periodic breathing, should be presumed to have depressed controls of breathing warranting assisted ventilation.

Failure of Neural Control

The brain may fail to drive rhythmic breathing for a variety of reasons. The brain is susceptible to injury, ischemic stroke, central nervous system hemorrhage, suppression of brain function by cold, structural dysfunction, chemical suppression, signal disruption, and intrinsic disorders of respiratory control. Efferent neural pathways may be blocked by spinal cord lesions, spinal anesthesia, phrenic nerve injury, or neuromuscular disorders. Examples are cited in Table 47.2.

TABLE 47.2
Causes of Failure of Neural Control of Breathing

Mechanism	Example
Brain injury	Closed head trauma
	Ischemic stroke
Severe supratentorial stroke	"Locked-in" syndrome (loss of volitional control of breathing)
Lateral medullary stroke	Ondine's curse (loss of automatic control)
Subarachnoid hemorrhage	Intracranial hypertension with uncal herniation
Brain suppression by cold	Cold-water drowning
Structural brain dysfunction	Brain stem glioma
Chemical suppression	Narcotic overdose
Signal disruption	Seizure
Intrinsic Disorders	
Idiopathic	Ondine's curse

Immaturity	Apnea of prematurity
Spinal cord lesion	Poliomyelitis, traumatic cord transection
Spinal anesthesia	Inadvertent spinal anesthesia
Phrenic nerve injury	Cardiac surgical phrenic nerve injury
Neuromuscular disorder	Curare poisoning, botulinum, and many snake venoms

Note that volitional and automatic control of breathing may be separately and independently affected. In Ondine's curse (resulting from stroke involving the lateral medulla), automatic control is impaired, whereas volitional control may persist in the awake state. Supratentorial stroke may impair volitional control of breathing, though automatic control of breathing may be preserved. Central hypoventilation is abnormal respiratory control by the brain and results in hypercapnia. Patients with central hypoventilation may have otherwise normal neurologic functioning or concomitant neurologic injury. Unless mixed with peripheral neuromuscular disease, patients have normal muscle strength, but the essential feature is altered responses to respiratory acidosis.[23] Respiratory patterns may also be abnormal. Central hypoventilation is most apparent when patients are sleeping. Apnea of prematurity, which may persist beyond term, is still not well understood but is clearly aggravated by concomitant infection.

Peripheral (extracranial) neural disorders include spinal cord injury, myasthenia gravis, anticholinesterase poisoning, and Guillain Barré syndrome. The hallmark of these diseases is muscle paresis or paralysis. Hypercapnia is a common feature. Depending on the extent of weakness, patients will be unable to increase their work of breathing in the face of lung disease. Clinical signs such as tachypnea and accessory muscle usage cannot be relied on. Abnormal arterial blood gases may be the only indications of worsening breathing failure, especially in patients with altered sensorium. Patients with spinal cord lesions develop muscle weakness below the level of injury. For instance, patients with lower cervical cord injury may have preservation of suprasternal muscle action but have loss of other accessory muscle function, as well as diaphragmatic dysfunction or paresis. These patients will have vigorous suprasternal retractions that expand the lung apices but have little other movement.

Failure of Muscles of Breathing

Causes of breathing muscle failure are listed in Table 47.3, along with examples. They may be crudely divided into causes of muscle exhaustion, causes of muscle plegia or paralysis, and causes of muscle tetany.

TABLE 47.3
Causes of Muscle Failure

Mechanism	Example
Overwork	Lung dysfunction, airway obstruction
Inadequate substrate	Shock, hypoxemia
Muscle plegia	Hypokalemia
Muscle tetany	Tetanus, hypocalcemia

In pediatric critical care, the most common cause of failure of the muscles of breathing is exhaustion. The respiratory muscles may become exhausted when responding to excessive workload. Airway obstruction (fixed or functional), lung stiffness, thoracic stiffness (eg, anasarca), abdominal distension, air trapping, and

inefficient ventilation-perfusion matching (eg, high ventilation-perfusion mismatch, which functionally wastes ventilation) are examples. Respiratory muscles may also become exhausted if their effort is not supported by adequate nutrition, blood supply, and oxygen delivery. Respiratory distress can be likened to running a marathon. There can be a “wall” beyond which respiratory muscle metabolism is not able to sustain further respiratory effort. Without assistance, after these muscles reach their “wall,” respiratory arrest occurs.

In both shock and hypoxemia, oxygen delivery to respiratory muscle may prove inadequate to meet demand on a minute-by-minute basis.[24] Skeletal muscle may sustain a transient oxygen debt by unloading oxygen from myoglobin, but such reserve is limited. Skeletal muscle can also perform anaerobic metabolism to generate adenosine triphosphate, but only until levels of reducing substances (diphosphopyridine nucleotide) build up to such a degree that they inhibit the activity of Kreb cycle enzymes. Over a range of oxygen delivery, metabolic use of oxygen is insensitive to rates of supply (delivery), but below some threshold, muscle aerobic metabolism must inevitably be reduced.[25]

Mitochondrial dysfunction may aggravate deficient muscle metabolism in sepsis. Impaired oxygen utilization may contribute to failure of breathing in other mitochondrial crises as well. One of the indications for intubation and mechanical ventilation in patients with septic shock is to avert respiratory arrest from failure of oxidative metabolism and exhaustion of the muscles of breathing.

There are a few conditions in which muscle contraction may be impaired by dysfunction of the myocyte. Tetrodotoxin (puffer fish) blocks the fast voltage-gated sodium channel of the muscle cell, thereby causing paralysis. Hypokalemia may impair muscle contraction, and hypokalemic periodic paralysis has similar effects. Tetanus and hypocalcemia are capable of causing tetanic contraction that can impair breathing.

Failure of Mechanics of Breathing

Mechanical factors may pose acute or chronic impediments to breathing. Some place such a burden on respiratory muscles that they become exhausted (eg, flail chest, severe thoracic dystrophy, chest deformity). Others cannot be overcome by any effort (eg, foreign body, pneumothorax). Chest and spinal deformities, diaphragmatic eventration, prune belly syndrome (in which abdominal musculature is virtually absent), and deformities that flatten the diaphragm may either cause chronic respiratory insufficiency or contribute to intolerance of intercurrent processes such as pneumonia.

Breathing Failure From Lung Disease

Acute lung disease may progress to breathing failure along one of several pathways. The primary mechanism is respiratory muscle exhaustion. Both excessive demand and impaired supply may come into play, and, in many children, poor thoracic mechanics and neurologic impairment contribute to breathing failure from acute lung disease.

Typically, lung disease increases the work of breathing. Hypoxia and hypercarbia drive the respiratory muscles toward exhaustion. Efficiency of the respiratory system

is impaired by lung regions of high ventilation-perfusion ratio. Because these regions see scant blood flow, they actually waste ventilation and breathing effort. On the other hand, low ventilation-perfusion ratio segments cause hypoxemia, which impairs oxygen delivery to tissue and makes circulation inefficient. When oxygen delivery is too low, muscle oxygen utilization becomes delivery dependent, and muscle work capacity declines. Add to these factors others, such as the compliance of the infant chest (which wastes breathing effort), the deformity of kyphoscoliosis (which makes breathing less efficient), the inefficiency of the infant diaphragm that operates at a wide angle to the chest wall, abdominal distension (which further widens that angle and opposes descent of the diaphragm), and the nutritional issues of chronic illness, and progression toward respiratory arrest is accelerated. Superimposed immaturity, neuromuscular dysfunction, or other comorbid conditions may also exacerbate breathing failure.

As breathing failure worsens, fatigue causes the patient's respiratory effort to deteriorate. Patients use accessory muscles less, they develop brief respiratory pauses, and they progress to apnea followed by respiratory arrest. Respiratory pauses are a subtle but helpful warning sign that should be interpreted as impending respiratory arrest. Pauses warn that respiratory support is indicated. Another helpful sign is grunting. Grunting is a low-pitched sound produced by partial or total closure of the glottis in expiration. Grunting is thought to augment expiratory lung volume (FRC) and increase arterial oxygen tension much like positive end-expiratory pressure (PEEP).[26] Grunting is also a warning of possible impending arrest in children and adults with respiratory failure,[27] though it also often occurs immediately after birth and may quickly resolve as the neonate successfully navigates transition. Patients may appear anxious and describe a feeling of air hunger. Mental status changes ranging from panic to obtundation may occur. Abrupt respiratory slowing and gasping are harbingers of respiratory arrest.

Ventilator-induced lung injury (VILI) and the acute respiratory distress syndrome are histologically inseparable. Two of the mechanisms of VILI are excessive tidal volume and repeated opening and closing of diseased lung units (see Chapter 51). The distress of breathing failure drives breathing. This exertion may overdistend some lung units while contributing to closure and reopening of others. The ausculatory finding of rales in patients with pneumonia supports the contention that closure and reopening of lung units are characteristic of parenchymal lung disease. Ventilation-perfusion mismatch suggests the presence of both overdistended and collapsed alveoli. One must ask: Can spontaneous breathing during respiratory failure promote an injury identical to VILI? Can spontaneous breathing of the patient with severe lung disease and breathing failure worsen lung mechanics and accelerate breathing failure?

After a patient has been intubated for breathing failure, tidal volume can be controlled, alveoli can be stinted open by PEEP, and the risk that superimposed secondary lung injury may worsen lung disease may actually be reduced (compared with the risk of an analogous injury by spontaneous breathing). Intubation also interrupts the progression from breathing failure to respiratory arrest.

Restrictive Versus Obstructive Respiratory Disease

Though restrictive and obstructive pulmonary processes act through the same final

common pathways of breathing failure, their mechanics and clinical manifestations often differ. Restrictive diseases are those that limit lung expansion. These include processes that (1) fill alveoli with blood, infectious material, edema, or other debris; (2) involve expansion or swelling of the alveolar interstitium; (3) compress the lung, as with pneumothorax or effusion; or (4) impair excursion of the chest wall or thoracoabdominal region because of neuromuscular dysfunction, skeletal deformity, abdominal distension, ascites, or anasarca. These processes are characterized by a reduction in vital capacity, small resting lung volumes, but normal or near-normal airways resistance. The physical examination reflects these processes. Patients are tachypneic, taking rapid, shallow breaths. Auscultation of the chest may reveal fine inspiratory crepitations (crackles) or rales, evidence of parenchymal lung disease. Poor excursion of the chest wall is usually readily appreciated. Retractions (subcostal and intercostal) are common and indicate significant respiratory effort.

Obstructive diseases of the lung are common in childhood and are characterized by obstruction to flow in airways. Obstructive diseases may be classified as extrathoracic (above the thoracic inlet) or intrathoracic (below). Obstruction may be the result of occluding material or tissue in airways, reduction in lumen caliber from elevated tone of the smooth muscle of airway walls or swelling of tissue, weakness of the airway wall causing collapse and impeding gas flow, or extrinsic compression of airways. In some diseases, several of these processes occur simultaneously. Indeed, secondary obstruction is a common phenomenon. Obstruction in a proximal airway may cause turbulent gas flow downstream in distal airways. Turbulent gas flow causes the wall of the still developing airway to flutter, further weakening the wall's structure and exacerbating overall obstruction.

The hallmark of extrathoracic obstruction is inspiratory noise (stridor or stertor). The affected airway segment lies between the nose and proximal trachea. Inspiratory stridor is a vibratory sound heard because the reduction of intrathoracic pressure during inspiration narrows the extrathoracic (subglottic) airway, generating an inspiratory noise. Stertor is a snoring noise generated in the nasopharynx. Airways with severe obstruction flutter in both inspiration and exhalation, causing biphasic stridor or noise heard in both phases of the respiratory cycle. Other characteristic sounds may help to identify the obstructed airway segment (Table 47.4). In extreme obstruction, patients may position themselves to maximize airway caliber (remaining upright, leaning slightly forward, and holding the head in the "sniffing position" to enhance alignment of the pharynx and larynx). It should be noted that generation of noise requires airflow. With severe obstruction, there is little airflow and little noise is generated. Loss of noise, despite increased effort, is an ominous sign and is indicative of complete obstruction and impending respiratory arrest.

TABLE 47.4

Abnormal Sounds Indicative of Extrathoracic Airway Obstruction

Sound	Condition
Hoarseness	Unilateral vocal cord paralysis
Muffled voice	Supraglottic or infraglottic processes, including epiglottitis
"Hot potato" voice	Oral, retropharyngeal abscess
	Cellulitis or connective tissue infection of the floor of the mouth also known as Ludwig's angina
"Barking" cough	Laryngotracheobronchitis (croup)
Monotone, hurried	Bilateral vocal cord paresis

sentences	

The hallmark of intrathoracic obstruction is an expiratory sound. In intrathoracic obstruction, forced expiration compresses soft airways, causing a musical wheeze. This obstruction may be largely relieved by inspiration, which tends to dilate intrathoracic airways. In severe intrathoracic obstruction, sounds may be heard during both phases of the respiratory cycle. The classic pediatric disease of intrathoracic obstruction is asthma. High-pitched wheezes on exhalation are heard early in the episode. As airway obstruction worsens, wheezes are heard in inspiration as well. With severe obstruction, wheezes diminish because there is little gas flow.

The character of the voice and ability to speak (in words, phrases, or sentences) may be helpful in the evaluation of airway obstruction. Observation of the respiratory rate can be revealing in obstructive disease. With mild obstruction, the respiratory rate is often slower than normal but may rise as ventilation perfusion inequality develops and increases respiratory drive. Physical examination will often reveal the use of accessory muscles of breathing.

Compensatory Mechanisms in Breathing Failure

A patient may try to compensate for the functional effects of lung disease. These compensatory mechanisms generally come into play before there is evidence of breathing failure. Many of the clinical signs of respiratory distress, discussed previously, are evidence of compensatory mechanisms. Understanding these mechanisms improves in the recognition of impending failure.

Compensatory Mechanisms in Restrictive Lung Disease

Tachypnea is the patient's primary compensation for the small lung volume of restrictive lung disease and is the earliest detectable clinical sign. Additional compensation is achieved by recruitment of accessory muscles. Patients with restrictive disease may take periodic sigh breaths, which are larger than tidal breaths, to recruit collapsing units. Compensatory mechanisms also operate to maximize gas exchange in diseased lungs. Hypoxic pulmonary vasoconstriction is an important mechanism to improve gas exchange in normal lungs. Hypoxic pulmonary vasoconstriction is a direct response of the vascular smooth muscle to low PaO_2 alveolar units. The precapillary arteriole of such units constricts in response to low O_2 tension in the adjacent postcapillary venule, thereby directing blood away from poorly functioning alveoli. In a lung with patchy disease, the overall effect of the hypoxic pulmonary vasoconstriction response is to shunt blood away from diseased segments and allow flow to healthier areas. This may, paradoxically, increase pulmonary vascular resistance and oppose right ventricular ejection. Inhaled nitric oxide (iNO) provides a putative exogenous means to improve ventilation perfusion matching (by preferentially dilating vessels to ventilated lung segments) without afterloading the right ventricle, although enduring benefits with iNO have not been demonstrated.[28]

Compensatory Mechanisms With Obstructive Lung Disease

The major compensations in obstructive disease focus on maximizing airflow. As

previously stated, patients naturally position themselves to maximize opening of their airway. If this is the case, repositioning patients, especially to the supine position, may worsen airflow. For the infant, carefully monitored prone positioning may aid gas exchange and assist spontaneous breathing.[29,30] Control of respiratory rate provides another means of compensation. In mild obstructive disease, the respiratory rate is lower than normal. As resistance to airflow rises, total work of breathing also rises greatly. To maximize efficiency, the respiratory rate falls. Longer respiratory cycle times allow longer times for gas flow. Having said this, the clinician will recognize that many patients with obstructive lung disease present with tachypnea, not decreased respiratory rates. The causes of tachypnea are (1) ventilation/perfusion mismatching with hypoxemia, and sometimes hypercarbia, driving the respiratory rate and (2) development of atelectasis in unventilated lung segments resulting in the superimposition of a restrictive process on an obstructive one. Tachypnea in such patients is counterproductive, greatly increasing the work of breathing and further diminishing gas flow.

Special Conditions

Several conditions deserve special note. In these, physical findings may reflect specific aberrations that generate specific compensatory mechanisms.

Infancy

Young infants are at a mechanical disadvantage for efficient breathing. The configuration of the infant's chest wall differs from that of adults. Orientation of the ribs is more horizontal in infants than in adults, and they move less during breathing. The chest wall is more compliant and is composed of more cartilaginous tissues. Strength of intercostals muscles is less. In the absence of muscular action, FRC is determined by the elastic forces of the lung and the chest wall, which oppose each other. Accordingly, the infant's more compliant chest wall and weaker musculature results in lower FRC. Infants with lung disease use expiratory braking (grunting), which involves constriction of pharyngeal muscles and glottis, to increase end-expiratory lung volume. Although this promotes higher FRC, it imposes a disadvantageous increase in muscular work.

Infant respiratory muscle fibers differ from those of adults. The infant diaphragm contains a greater proportion of type II fibers, which are unable to sustain repeat strenuous activity.[31] Hence, the infant's diaphragm fatigues more quickly than that of the adult.[32] The infant's diaphragmatic anatomy is also disadvantageous. The reduced appositional area and greater diaphragmatic angle of the infant causes less lung volume expansion with diaphragmatic contraction. Because pulling the rib cage cephalad produces less outward chest displacement in the infant than in the adult, the infant's tidal volume is, in the aggregate, more dependent on diaphragmatic contraction than that of the adult.

Superimposition of breathing failure on infant respiratory function exacerbates these mechanical disadvantages. In normal respiration, the chest wall and abdomen move inward and outward in synchrony. With restrictive lung disease, the respiratory pattern may be out of phase, called *paradoxical breathing*. Contraction of the diaphragm pulls the compliant infant chest wall inward during inspiration and pushes abdominal contents outward. This respiratory pattern is greatly exaggerated

by severe restrictive lung disease. With decreased lung compliance, the pleural pressure swing is exaggerated, pulling the chest wall farther inward. Prolonged respiration in this manner can cause inward deformation of the sternum, or acquired *pectus excavatum,* and is a clinical sign of prolonged respiratory insufficiency. In the infant with severe restrictive disease, recruitment of additional diaphragmatic and accessory muscles, use of compensatory braking and grunting maneuvers, and increases in respiratory rate may be insufficient to maintain a normal FRC. Fatigue comes quickly. Moreover, such work is extremely energy expensive. Infants with chronic respiratory insufficiency can use as much as 50% of their caloric intake for breathing, leaving few calories for growth and other functions and resulting in failure to thrive.

Infants are disadvantaged with respect to obstructive lung disease. In infants and young children, a greater percent of total airways resistance is apportioned to large airways than in adults. Infants are particularly susceptible to nasal obstruction, as occurs during upper respiratory infection, because the nose may comprise as much as 50% of total airway resistance. Moreover, resistance to airflow is proportional to the inverse of the airway radius to the fourth power:

$$R = 8\eta L/\pi r^4$$

where η is gas viscosity, L is airway length, and r is radius of the airways. Resistance is greater in infants and young children because of their intrinsically small airways. Further reduction in airways caliber with obstructive disease (eg, bronchiolitis) magnifies this problem.

The infant's airways are also less endowed with cartilage than are those of the adult and may be subject to flow limitation during active expiration. The trachea and bronchi may be pathologically compressed during expiration, causing severe obstruction that is worsened by expiratory effort. Such regions of severe and pathologic flow limitation (tracheomalacia and bronchomalacia) may be localized. Similarly, the larynx may be compressed (by atmosphere) during forced inspiration (laryngomalacia) if there is proximal (supraglottic) obstruction.

Thoracic Dysfunction

Neuromuscular disorders generally result in restrictive lung defects. Coexisting obstructive lung disease can be seen with some thoracic defects or with scoliosis. Persistent atelectasis and long-standing lung hypoplasia may lead to atrophy and may destroy supporting airway architecture resulting in air trapping. Deformities of the rib cage and spinal column result in restriction to lung expansion as occurs with isolated scoliosis.[33,34] The most severe of these are classified as “asphyxiating thoracic dystrophies” in which the chest fails to expand at all during breathing. As with the other forms of neuromuscular diseases, hypercapnia predominates. Muscle strength may be normal, but abnormal configuration of intrathoracic muscles and diaphragm may make muscle work inefficient.

With many of these disorders, patients live in a chronic state of increased work of breathing and muscle fatigue. Growth failure is common. They tend to have little ability to meet the added demands of acute respiratory processes, such as respiratory infections. Total breathing failure often ensues. They may have frequent

and recurring need for positive pressure support. Yet the usual signs of impending breathing failure may be absent in patients who are weak, nonresponsive, or have chest wall distortions. In such cases, close monitoring and measurement of arterial blood gases are essential.

Altered Nutritional States: Malnutrition and Obesity

A major functional consequence of malnutrition is altered muscle function. Protein-calorie malnutrition results in decreased muscle energetics.[35] Protein deficiencies alone may have a similar effect. Catabolism of skeletal muscle to meet body protein needs results in decreased muscle mass. Malnourished states are easy to recognize when they are the result of long-standing inadequate caloric intake, as in marasmus, but this is rarely seen in developed countries. More common are subtler forms of insufficient nutrition in children who live in a chronically high metabolic state, such as chronic congestive heart failure. Such patients may be unable to consume enough calories for effective positive nitrogen balance. Catabolism is ongoing, sacrificing muscle mass and function. Chronic respiratory insufficiency results in a cycle of progressive breathing failure, increasing work of breathing, and worsening imbalance between calorie intake and expenditure. Recognition of this cycle is imperative; metabolic demands must be decreased by treating the underlying condition and caloric intake must be increased. In the young child, reversal of this cycle is signaled by resumption of somatic growth. The clinician should also note that in patients with malnutrition the superimposition of an acute respiratory process, such as an intercurrent respiratory infection, will result in more rapid progression to breathing failure. The patient has little or no reserve for the added metabolic demands and work of breathing.

At the other end of the nutritional spectrum, obesity has major respiratory consequences. As with obese adults, obese children are at risk from obstructive sleep apnea syndrome. Obstructive sleep apnea syndrome may cause frequent obstructive events. Hypercarbia and hypoxemia may occur. Obstructive sleep apnea syndrome is diagnosed by polysomnography. Treatment includes weight loss, removal of tonsils and adenoids, palatoplasty procedures in some patients, and nightly positive pressure support in others. Additionally, obesity alters lung volumes, especially when children are supine. With abdominal contents pushing up on the diaphragm, FRC and total lung capacity are reduced, representing another form of chronic restrictive disease. This effect is exaggerated in the supine (as opposed to upright) position.

Conclusion

Breathing failure occurs when neural, muscular, or mechanical challenges cannot be overcome by compensatory mechanisms. A common final pathway is muscle exhaustion, either from excessive demand on respiratory muscles or from inadequate supply to these muscles of blood flow, oxygen, or nutrients. Assisted ventilation is important to not only improve gas exchange but also prevent respiratory arrest from breathing failure. This is true in both lung disease and other conditions that impair neural, muscular, or mechanical breathing capacity.

CHAPTER 48

Ventilation/Perfusion Inequality

Thomas V. Brogan, David J. Vaughan

PEARLS

- Gravity affects the distribution of pulmonary blood flow and ventilation. Both perfusion and ventilation increase down the lung. Despite these changes, perfusion is tightly matched to ventilation.
- There is also significant heterogeneity of pulmonary blood flow and ventilation in isogravitational fields. The pattern of both perfusion and ventilation is fractal in nature.
- The primary ventilation/perfusion abnormality in acute respiratory distress syndrome (ARDS) is intrapulmonary shunt.
- In persons with asthma, ventilation/perfusion mismatch is responsible for hypoxemia, but no correlation exists between measurements of overall airway obstruction and V_A/Q mismatch.
- Although positive end-expiratory pressure decreases the proportion of shunt in ARDS, at high levels it also increases dead space.

The primary function of the lung is to exchange oxygen and carbon dioxide between inspired air and blood. Efficient gas exchange requires the close matching of regional ventilation and perfusion. The lung is influenced by external and internal factors that affect ventilation/perfusion (V_A/Q) relationships. Early studies supported the concept that vertical gradients of both ventilation and perfusion produced close V_A/Q matching. Newer studies demonstrated that perfusion and ventilation have much greater heterogeneity, even in isogravitational planes, which serves to match ventilation to perfusion.

Lung diseases commonly produce abnormalities in functional residual capacity (FRC) and closing capacity, which distort normal V_A/Q matching (Table 48.1). Lung units that are poorly ventilated in relation to blood flow (low V_A/Q) produce blood with low oxygen content (desaturated blood), but units with high V_A/Q ratios cannot compensate because the oxygen content of blood leaving these areas has oxygen

content only slightly higher than that from normal V_A/Q regions due to the sigmoid shape of the hemoglobin oxygen dissociation curve (Fig. 48.1).

TABLE 48.1

Causes of Hypoxemia

Intrapulmonary Factors	Extrapulmonary Factors
PRIMARY	PRIMARY
Ventilation/perfusion mismatch	Decreased cardiac output
Shunt	
Alveolar-end capillary diffusion limitation	SECONDARY
	Decreased P50
Decreased minute ventilation	Decreased hemoglobin concentration
Decreased Fio_2	Alkalosis

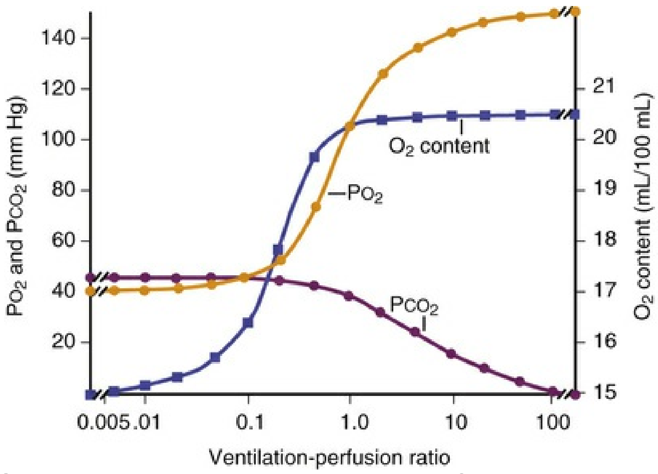

FIG. 48.1 Gas exchange in a single lung unit. Changes in P_{O_2}, P_{CO_2}, and end-capillary O_2 content in a lung unit as its ventilation/perfusion ratio is increased from shunt (V/Q = 0) to dead space (V/Q = ∞). Hemoglobin concentration is 14.8 g/dL.

The alveolar gas equation helps to explain the pathophysiology of abnormal gas exchange by providing information on alveolar oxygen tension. According to the Fick equation, under steady state conditions, the quantity of O_2 taken up by the lungs equals the amount of O_2 removed from inhaled air:

$$O_2 = {}_A(FIO_2 - FAO_2) \qquad \textbf{Eq. 48.1}$$

where O_2 represents O_2 consumption, FIO_2 is the fraction of inspired O_2, A represents alveolar ventilation, and FAO_2 is the fraction of alveolar O_2. This equation can be rearranged to read:

$$FAO_2 = FIO_2 - O_2/{}_A \qquad \textbf{Eq. 48.2}$$

Then, by changing the fraction of gases to their partial pressures, the equation

takes the following form:

$$PAO_2 = PIO_2 - (O_2/_A)(P_B - 47 \text{ mm Hg}) \qquad \textbf{Eq. 48.3}$$

where PIO_2 is the inspired PO_2 and P_B is barometric pressure.

The concept underlying this equation is that alveolar oxygen level (PAO_2) is the difference between inspired oxygen (PIO_2) and the amount taken up by the pulmonary capillaries $[(O_2/_A)(P_B - 47 \text{ mm Hg})]$. The ratio $O_2/_A$ can be estimated from a surrogate for the ratio between O_2 and $_A$. By using PCO_2 in arterial blood as an estimate of alveolar CO_2, $CO_2/_A$ as an estimator of $FACO_2$, and the respiratory quotient $R = CO_2/O_2$, the second term of Eq. (3) can be estimated by $PACO_2/R$. The alveolar gas equation can then be derived as follows:

$$PAO_2 = FIO_2 \times (P_B - 47 \text{ mm Hg}) - (CO_2/R/_A) \times (P_B - 47 \text{ mm Hg}) \qquad \textbf{Eq. 48.4}$$

$$PAO_2 = FIO_2 \times (P_B - 47 \text{ mm Hg}) - (F_ACO_2/R) \times (PB - 47 \text{ mm Hg}) \qquad \textbf{Eq. 48.5}$$

$$PAO_2 = FIO_2 \times (P_B - 47 \text{ mm Hg}) - (PACO_2/R) \qquad \textbf{Eq. 48.6}$$

According to this equation, PAO_2 may be decreased by increases in the $PACO_2$ or by decreases in the atmospheric pressure and R.

Distribution of Ventilation

Regional lung ventilation is influenced by many factors, including gravity, posture, and experimental technique. Gravity has been considered paramount because it creates variation in pleural pressure from the lung apex to the base, imposing a globular shape on the lung. Pleural pressure is more negative at the apex of the lung compared with the base, increasing approximately 0.25-cm H_2O per centimeter of vertical distance toward the base, making transpulmonary pressure greater at the apex. Consequently, apical alveoli are large, at the upper end of the normal pressure volume curve, and distend less for a given pressure change (lower compliance). In the spontaneously breathing upright human, maximal gas distribution occurs at the base and progressively diminishes toward the lung apex.[1,2] This gradient also exists when inhalation occurs in the recumbent position, although to a lesser degree.

Ventilation heterogeneity does not depend solely on gravitational influences. The time constant (the product of resistance and compliance) is the time required for inflation to 63% of final lung volume. Therefore a given lung unit with a slow time constant fills more slowly than one with a fast time constant and empties more

slowly. When time constants of different lung units vary, as frequently happens in lung disease, gas distribution will be determined in part by the rate, duration, and frequency of breathing.

Distribution of Perfusion

The pulmonary circulation is a low-pressure circuit with a mean pulmonary artery pressure (P_{PA}) of approximately 15 mm Hg, compared with mean systemic pressure on the order of 100 mm Hg. According to the classical model of lung perfusion, gravity affects PBF in a similar fashion to ventilation but to a greater extent. The P_{PA} decreases by 1 cm H_2O per centimeter of vertical distance up the lung, so the driving pressure rapidly drops with minimal blood flow to the apices. In the erect human, pulmonary blood flow (PBF) progressively increases from apex to base.[3]

The three-zone model of PBF has been widely used to explain the heterogeneity of perfusion within the lung (Fig. 48.2).[3] Three variables comprise the components of this model: pulmonary arterial (P_{PA}), alveolar (P_A), and pulmonary venous (P_V) pressures. PBF within the lung zones depends on the relative magnitudes of these pressures within each zone. Zone 1 ($P_A > P_{PA} > P_V$) has negligible blood flow, as high alveolar pressure is believed to compress collapsible capillaries. This region is one of minimal gas exchange or "wasted" ventilation. Zone 1 conditions are rare except in cases of diminished PBF (eg, hypotension or cardiac failure) or increased P_A encountered during positive pressure ventilation.

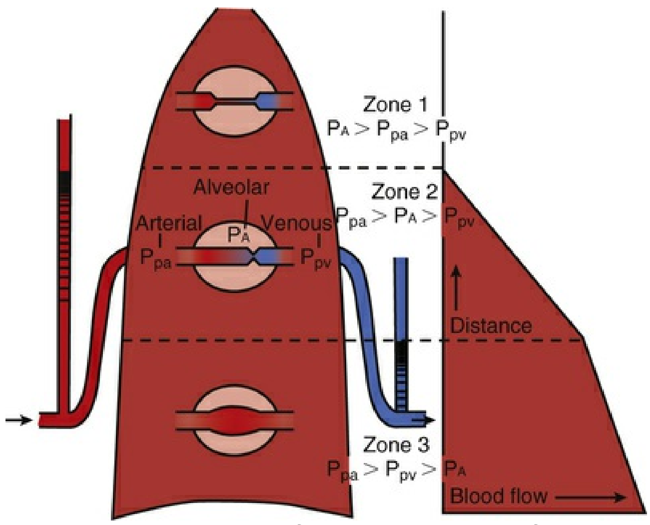

FIG. 48.2 Normal distribution of pulmonary blood flow: gravitational model. According to the model, the gravitational driving force for pulmonary blood flow increases down the lung. At the apex (zone 1), flow is absent as alveolar pressure *(P_A)* exceeds pulmonary artery *(P_{PA})* and pulmonary venous *(P_V)* pressures. In *zone 2,* flow is determined by the driving pressure ($P_{PA} - P_A$). Flow is constant and maximal in *zone 3* because both P_{PA} and P_V exceed P_A where the driving pressure is $P_{PA} - P_V$.

Zone 2 consists of the midportions of the lungs in which $P_{PA} > P_A > P_V$, where PBF is determined by the difference between pulmonary arterial and alveolar pressures. Venous pressure does not influence the flow rate. Blood flow progressively increases with descent through this zone as P_{PA} increases, whereas P_A remains relatively constant.

In the lowest lung region, zone 3, $P_{PA} > P_V > P_A$; therefore the arteriovenous pressure gradient ($P_{PA} - P_V$) determines PBF.[3] A zone 4 region in the most dependent areas of the lung has also been described. In this region, transudated pulmonary interstitial fluid increases interstitial pressures, thereby reducing blood flow; this effect is exaggerated as lung volume diminishes from total lung capacity to residual volume.

PBF in immature animals differs in several important ways from that of adult animals. The immature pulmonary vascular bed appears to be fully recruited, with no contribution of Starling resistors in the pulmonary circulation during exposure to acute or chronic hypoxia.[4,5] Furthermore, neonatal piglets show a relative hypoxemia with an increased dispersion of PBF.

Fractal Model of Pulmonary Blood Flow and Ventilation

Studies employing increased resolution showed PBF to possess greater heterogeneity than described in the gravitational model.[6-8] Isogravitational PBF was shown to be nearly as heterogeneous as that of the entire lung (Fig. 48.3) rather than being random PBF correlated with that of neighboring regions.[8] High-flow regions bordered other high-flow regions while low-flow regions abutted other low-flow regions. The distribution of PBF was shown to be independent of the scale of measurement, suggesting a fractal nature of PBF.

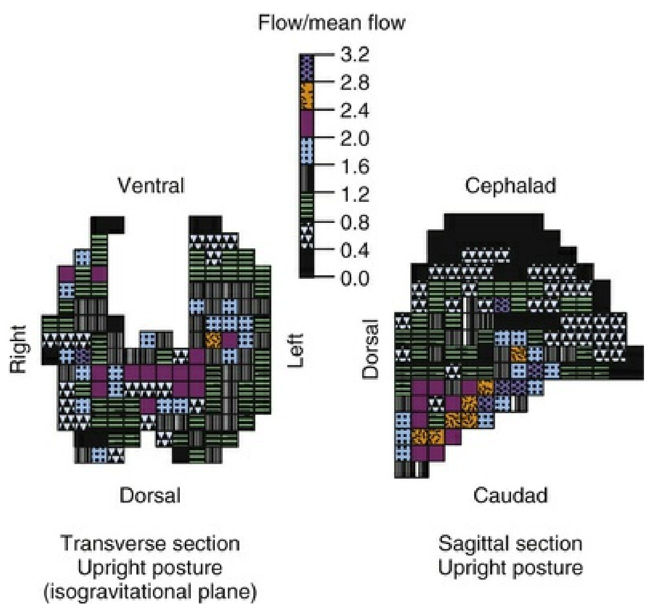

FIG. 48.3 Isogravitational heterogeneity of pulmonary blood flow. Reconstruction of transverse and sagittal plane from a single baboon

animal during upright posture. Each *square* depicts location and relative blood flow to a piece of lung in a given plane. Heterogeneity of blood flow is present in isogravitational planes. Flow is not random; rather, neighboring pieces tend to have similar magnitudes of flow. Cephalad-caudad (gravitational) gradient is apparent in the sagittal section.

A fractal structure or process has a characteristic form that remains constant over a magnitude of scales (Fig. 48.4).[8] This concept of self-similarity has been recognized within the bronchial and pulmonary vascular trees.[9] In animal models and in humans under conditions of microgravity, gravity's contribution to overall perfusion heterogeneity was of secondary importance. PBF had a hilar to peripheral gradient.[9-11] The asymmetry of flow at pulmonary artery branches accounts for the heterogeneity of flow within isogravitational planes. Thus regions that share a parent or grandparent branch have more similar flows than do branches that are separated by a greater distance. This fractal pattern extends to the subacinar level.[12]

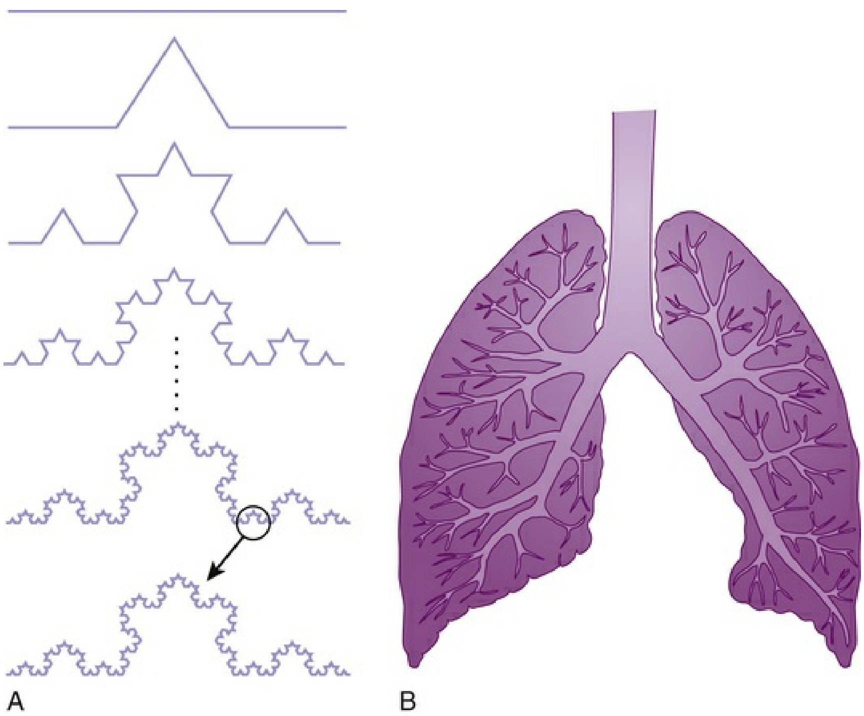

FIG. 48.4 Fractal structures. (A) This curve is produced by a simple iterative transformation beginning with a straight line. At each step the middle third of all lines is replaced with two segments, one-third length of the line, forming part of an equilateral triangle. An infinite number of iterations can be performed. Thus as increasing magnification reveals more detail, the overall appearance of the new segment remains similar to that of the previous segment. (B) The pulmonary vascular (and bronchial) tree is a repetitive pattern of dichotomous branches that become progressively smaller and fill a predetermined area.

Fractal Model of the Pulmonary Ventilation

The close correlation between regional ventilation and perfusion suggests that

ventilation has spatial characteristics similar to perfusion.[13-16] The correlation of regional heterogeneities of ventilation and perfusion ensures a narrow distribution of V_A/Q normally. Fractals possess a large area-to-volume ratio, ensuring that all cells are serviced by capillaries and efficiently ensuring gas exchange and substrate irrespective of an organism's size. The correlation between regional ventilation and perfusion may be explained by the close association of the developing bronchial tree and pulmonary arterial tree during organogenesis.[17]

The innate structure of the lung itself appears to underlie the precision of V_A/Q matching.[18] Basal pulmonary vascular tone is minimal, suggesting that vasoregulation is of minor importance for maintaining close V_A/Q matching normally.[19-21] Passive matching of perfusion and ventilation by pulmonary structure suggests that lung perfusion is an optimally engineered system. That is, it requires no active feedback mechanism during normal function, which tends to sustain effective performance (Fig. 48.5).[22] Furthermore, a fractal system delivers substrate with a minimum of energy expended because the fractal structure minimizes the total hydrodynamic resistance of the system, as well as the amount of biological material to construct the vascular and bronchial trees while still filling the space occupied by the lung.[22] Finally, the fractal structure efficiently uses the amount of genetic code to construct the vascular and bronchial structure by using a recursive construction mechanism that requires only a handful of proteins. A much greater amount of genetic code would be needed if each branch in the system required unique genetic code.

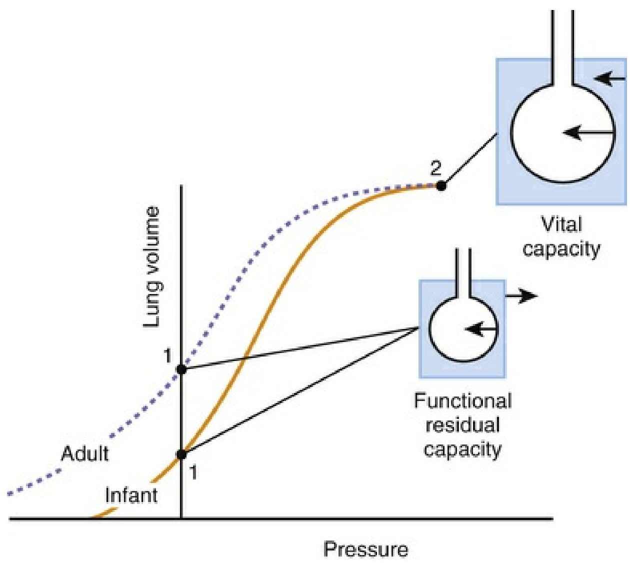

FIG. 48.5 Relative ventilation and perfusion maps. Regional ventilation and perfusion scaled to the measured minute ventilation and cardiac output in the pig. Both regional ventilation and perfusion show clustering in which adjacent units have similar flows. There is strong correlation in which areas of high ventilation receive high perfusion and areas of low ventilation receive low perfusion. (These pig lungs were examined in cubes of 1.5 to 2.0 cm^3 volume.)

V_A/Q Abnormalities in Pulmonary Disease

Hypoxemia

The primary causes of hypoxemia in children are intrapulmonary shunt and V_A/Q mismatch. Shunt differs from V_A/Q mismatch in that it does not respond to increases in inspired O_2. Oxygen content of arterial blood represents a weighted average of the O_2 content of shunted blood (Q_s/Q_t) and the remaining fraction ($1 - Q_s/Q_t$):

$$C_aO_2 = C_vO_2 \times Q_s/Q_t + C_cO_2 \times (1 - Q_s/Q_t) \quad \textbf{Eq. 48.7}$$

Q_s and Q_t represent shunt and total lung blood flow, respectively, and C_aO_2, C_vO_2, and C_cO_2 are the arterial, venous, and pulmonary capillary oxygen contents, respectively. This equation can then be rearranged to solve for shunt fraction:

$$Q_s/Q_t = \frac{C_cO_2 - C_aO_2}{C_cO_2 - C_vO_2} \quad \textbf{Eq. 48.8}$$

Regional alveolar hypoxia causes pulmonary vasoconstriction, restricting blood flow to the area.[23,24] (A similar though less robust response occurs with decreased mixed venous oxygenation [$P\bar{v}O_2$].) This compensatory response, hypoxic pulmonary vasoconstriction (HPV), is best when hypoxia is localized and when the P_AO_2 is in the 70 to 90 mm Hg range.[24] The degree of HPV varies across the lung and is affected by sepsis, vasodilators, anesthetics, and changes of inspired oxygen. Inspiration of 100% O_2 worsens V_A/Q mismatch substantially by opposing HPV.[25]

Alterations in inspired or arterial CO_2 tensions also have been shown to alter V_A/Q ratios. Inspired CO_2 (3%–5%) improves V_A/Q matching and perfusion heterogeneity in normal and injured lungs, while hypocapnia produces the opposite effect.[26-28] These changes in V_A/Q heterogeneity appear to be dependent on changes in pH.

Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) is marked by profound hypoxemia refractory to high FiO_2, suggesting shunt.[29] Hypoxemia in ARDS is due to shunt that is proportional to cardiac output.[29] Intrapulmonary shunt results from alveolar flooding, atelectasis, and right-to-left shunt through a patent foramen ovale. Some patients also have units with very low V_A/Q ratios as well as substantial ventilation to regions that are underperfused. The low V_A/Q units explain the increase in venous admixture with decreasing inspired fractional concentration of oxygen and may represent transient events that occur when alveoli are in the process of collapsing or reexpanding.[30] Units with low V_A/Q deteriorate to shunt as a result of absorption atelectasis, especially when exposed to high levels of FiO_2.

Pneumonia

Hypoxemia found in patients with pneumonia is multifactorial. Animal models of pneumococcal lobar pneumonia showed intrapulmonary shunt early in the course that evolved to perfusion of regions with low V_A/Q ratios.[31] Patients receiving mechanical ventilation for bacterial pneumonia had a combination of intrapulmonary shunt and increased perfusion to low V_A/Q units.[32] High F_IO_2 did not increase intrapulmonary shunt but did oppose HPV in pneumonia patients. Similar, less severe findings also were observed in spontaneously breathing patients with pneumonia.[33]

Asthma

Ventilation/perfusion abnormalities have been found across the spectrum of patients with asthma. Asthmatics usually have a bimodal distribution of blood flow with normal units and large areas of low V_A/Q with little intrapulmonary shunt.[34] No correlation exists between measurements of airway obstruction and inert gas exchange,[35] so maximum airflow rates and V_A/Q inequalities appear to be unrelated, suggesting that spirometric changes reflect bronchoconstriction in larger and medium-sized airways, whereas V_A/Q abnormalities are mainly related to edema and/or mucus formation occurring in the distal small airways.[35] High F_IO2 may prevent HPV and place low V_A/Q regions at risk for absorption atelectasis. Bronchodilators may enhance the perfusion of low V_A/Q areas, exacerbating V_A/Q mismatch. However, the beneficial effects of bronchodilators on airway resistance generally outweigh the worsening in V_A/Q mismatch.

Pulmonary Embolism

Pulmonary emboli tend to travel to high-flow regions of the lung, producing a shift of PBF toward regions that previously had seen low flow, preferentially in nondependent areas, which have greater capacity for capillary recruitment.[21] Before embolization, regions with high blood flow had good V_A/Q matching. After embolization, regional ventilation changed little. The areas to which blood flow shifted now became low V_A/Q regions, resulting in hypoxemia. Nonperfused areas added to dead space, increasing P_ACO_2.

Primary Pulmonary Hypertension

V_A/Q inequalities tend to be moderate even in late stages of pulmonary hypertension.[36] Much of the cardiac output is distributed to lung units with almost normal V_A/Q ratios, whereas less than 10% of flow perfused underventilated or unventilated areas. When Q is reduced, hypoxemia often occurs because of low mixed venous PO_2. Oxygen, sodium nitroprusside, isoproterenol, and nifedipine worsen V_A/Q matching, but patients do not usually experience hypoxemia due to increased flow, resulting in an increase in SvO_2 that raises end-capillary PO_2.

Therapeutic Considerations

Positive End-Expiratory Pressure

Positive end-expiratory pressure (PEEP) decreases the proportion of shunt units by recruiting atelectatic units, thereby improving FRC, closing capacity and oxygenation. By decreasing cardiac output (Q), PEEP also decreases intrapulmonary shunt. However, even when Q is preserved, PEEP decreases shunt because of increased flow to recruited units.[30] With constant Q, PEEP decreases venous admixture and increases P_vO_2.

PEEP also affects dead space. Low levels of PEEP decrease dead space by reductions in shunt, but high levels of PEEP increase dead space. The increase in dead space with high PEEP results from overinflation of some lung units, leading to compression of capillaries and zone 1 conditions.

Prone Positioning

Studies have shown that prone positioning, especially when employed early in the course of ARDS, improves survival, although this benefit remains undemonstrated in children.[37-39] Prone positioning improves oxygenation by producing more evenly distributed ventilation and an increase in the matching of ventilation to perfusion.[40-42] In ARDS and other lung injury models, nonaerated or poorly aerated portions of the lung are found mainly in the dependent areas. The majority of perfusion goes through dorsal lung regions, whether in the prone or supine position.[4] Positive pressure ventilation, especially PEEP, redistributes perfusion toward the dependent portion of the lungs by creating conditions of zones 2 and 1.[4,32] This redistribution may increase the vertical perfusion gradient in the supine position but may reduce it in the prone position.

Nitric Oxide

Nitric oxide (NO) improves gas exchange in persons with acute lung diseases by preferentially increasing blood flow to well-ventilated regions of the lung. NO reaches the well-ventilated units, producing vasodilation and reducing shunt fraction.[43] Beneficial effects appear over a wide range of doses. A randomized trial in children with ARDS showed a significantly greater extracorporeal membrane oxygenation-free survival in the inhaled NO group compared with controls.[44] NO does not appear to be beneficial in persons with chronic lung diseases, possibly because the structural damage precludes rapid vascular changes or because shunt usually is not found in such diseases.

CHAPTER 49

Mechanical Dysfunction of the Respiratory System

J. Julio Pérez Fontán

PEARLS

- Workload and efficiency define the demands that disease imposes on the respiratory muscles and therefore are the relevant variables in the analysis of the mechanical function of the respiratory system.
- The work done by the respiratory muscles and, by extension, the energy that must be supplied to these muscles are defined by the combined volume-pressure relationships of the lungs and chest wall.
- Volume changes within the respiratory system are dictated primarily by the body's need to take up oxygen and eliminate carbon dioxide and therefore are determined by factors such as physical activity or metabolic rate, which are relatively independent of the condition of the lungs and chest wall. Pressure changes, on the other hand, depend on physical processes that take place in the respiratory system's constituents.
- The efficiency of the respiratory pump is influenced by factors that the astute clinician must consider when assessing a child's ability to sustain an increased respiratory workload. These include the configuration of the diaphragm, presence of rib cage distortion, and nutritional state and conditioning of the respiratory muscles.
- It is a common clinical observation that different types of mechanical derangement result in distinctive patterns of breathing. These patterns generally agree with the principle of minimal power expenditure and can be useful to categorize the type of derangement the patient has during the initial evaluation.

From a mechanical perspective, the mammalian respiratory system functions like a reciprocating pump that aspirates fresh air into the pulmonary alveoli and exhausts spent alveolar gases into the atmosphere. The pump is powered by a specialized group of skeletal muscles (the respiratory muscles) that, through their insertions on the skeletal structures of the chest and abdomen, create movements that expand and sometimes compress the lungs. As often happens with systems that contain moving

parts, the respiratory system is particularly vulnerable to mechanical dysfunction. The inefficiencies imposed by this dysfunction and the attempts that the organism makes to compensate for them are responsible for the majority of the signs and symptoms of respiratory disease. Whether compensation occurs before the appearance of intolerable alterations in gas exchange and, if so, at what cost for the organism are the all-important questions that often define both the therapeutic course and ultimate outcome of respiratory disease at all ages. As we will see, both questions can be analyzed in the simple thermodynamic terms of a balance between the work that must be done and the energy that is available to do it.

This chapter provides a basic understanding of the mechanical function of the respiratory system in health and disease, focusing on factors that determine both respiratory work and energy expenditure. The first portion of the chapter discusses the forces responsible for the volume-pressure behavior of the lungs and chest wall and how this behavior relates to the work of breathing in both normal and disease conditions. The second portion analyzes the elements that influence the translation of the work of breathing into energy expenditure, with special attention to the factors that define the efficiency of the respiratory system. Throughout the chapter, the unique characteristics of the developing respiratory system and the mechanical features that are relevant for the diagnosis and management of respiratory disease are highlighted.

Work, Power, and Energy Expenditure in the Respiratory System

In simple intuitive terms, the variable that best sums up the function of a muscle-powered pump is the mechanical load that the contraction of the powering muscles must overcome with each pump cycle. Over time, mechanical load translates into power (the work divided by the time that it takes to carry it out) and energy expenditure. Accordingly, whether the respiratory muscles can carry a given mechanical load is ultimately determined by their ability to generate work from the limited amount of energy that they can mobilize from their blood supply. The first law of thermodynamics stipulates that when a certain amount of energy is added to a closed system by an external source (in this case the metabolism of fuels supplied by the circulation to the respiratory muscles), the resultant change in the system's internal energy may be either applied to perform external work (W) over a period of time (t) or dissipated as heat (Q). Implicit in this statement is the fact that only a portion of the energy that the respiratory muscles derive from metabolic substrates is transformed into respiratory work. This proportion varies depending on the system's efficiency (E), defined as:

$$E = \frac{W \cdot t}{W \cdot t + Q} \qquad \textbf{Eq. 49.1}$$

Thus workload and efficiency define the demands that the contractile machinery of the respiratory muscles must meet and therefore are the relevant variables in the analysis of the mechanical function of the respiratory system.

Determinants of Respiratory Work

Every high school physics student learns to calculate the external work done to move an object between two points as the product of the force needed to overcome all resistances to the movement by the distance between the points. Because the force may change along the way, the same student may learn at some point that it is more practical to break the movement into many elementary components and then add up all the work components by integration, as shown in Fig. 49-1A.

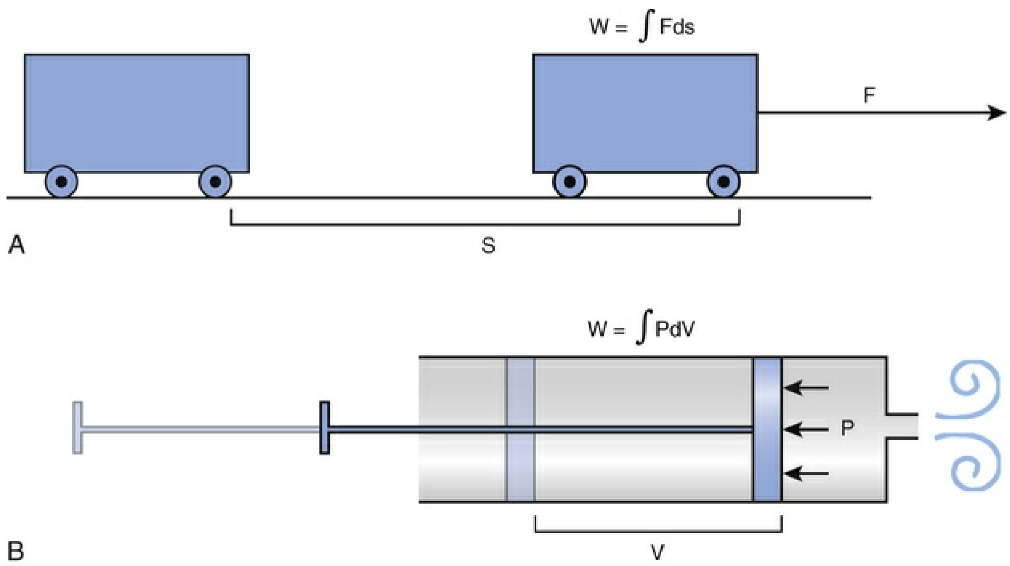

FIG. 49.1 (A) The amount of work that a force *(F)* must perform to move an object over a linear distance *s* is equivalent to the product *F* × *s*. If the force varies during the displacement, then it is more precise to integrate the product of F by the change in *s (ds).* (B) By analogy, the work needed to produce a volume displacement *V* in a syringe, a better analogy for the respiratory pump, is determined as the integral of the product of the pressure inside the pump (the tridimensional analog of *F*) by *dV* (the tridimensional analog of *ds*).

The calculation of the external work during breathing follows the same general principle, with one caveat: Allowances must be made for the fact that the lungs and chest wall move in all the dimensions of space. In other words, their displacements are measured in terms of volume, not distance, and determined by pressure, not force. The mathematic subtleties of this distinction may become a little clearer if we compare the breath to the action of a syringe, where, by pushing or pulling on the plunger, we create a pressure (P), positive or negative, that has the effect of changing the volume contained in the barrel (V). The work done in this process can be determined by integrating the product P • dV, as shown in Fig. 49.1B. The obvious corollary is that the work done by the respiratory muscles and, by extension, the energy that must be supplied to these muscles are both defined by the volume-pressure relationships of the lungs and the chest wall.

Volume-Pressure Relationships

Before analyzing the volume-pressure behavior of the various components of the

respiratory system, it is helpful to clarify the terminology. Throughout this chapter, the term *thorax* is used in reference to all the moving components of the respiratory system, including the walls of the thoracic cavity (the skeletal rib cage and its soft tissues), abdomen, and lungs themselves. Similarly, the term *chest wall* is used to indicate all the structures that form the enclosure of the lungs, including the thoracic wall, diaphragm, abdominal wall, and abdominal organs.

The volume changes of the respiratory system can be easily measured with the help of devices such as spirometers (which measure gas flow) or plethysmographs (which measure volume displacement). For any breath, the thorax (defined by the suffix TH), lungs (L), and chest wall (W) all undergo the same change in volume, or:

$$\Delta V_{TH} = \Delta V_{L} = \Delta V_{W} \qquad \textbf{Eq. 49.2}$$

This identity results from the manner in which the lungs and chest wall are linked at the pleural interface, which prevents them from changing volume independently of each other.

The pressures needed to inflate the thorax, lungs, and chest wall are, in contrast, different from each other. Respiratory physiologists have traditionally approached the analysis of these pressures by taking an imaginary walk from the mouth down the airways to the alveolus, across the lung tissue and visceral pleura to the pleural space, and finally across the chest wall to the surface of the chest (Fig. 49.2). In this path, we would first encounter gas (from the mouth to the alveolus) and then successive barriers of tissue (alveolar wall, lung interstitium, pleura, and skeletal and soft tissues of the chest wall). If we were to measure the local pressure at strategic points along the way, then we could easily apportion how the pressure generated by the respiratory muscles is used to mobilize the components of the respiratory system. This would be a useful exercise because it allows us to isolate the components that are performing poorly from a mechanical perspective and to quantify the extent of their dysfunction. For instance, the difference between the pressures measured at the mouth (P_M) and the alveolus (P_A) is the pressure needed to force air through the conducting airways (P_{AW}):

$$P_{AW} = P_M - P_A \qquad \textbf{Eq. 49.3}$$

An increase in this pressure above what is expected would alert us that there is undue resistance to the passage of air through the airways. Similarly, the difference between the pressures measured in the alveolus and the pleural space (P_{pl}) is the pressure required to overcome the forces that the muscles must overcome to inflate the lungs beyond their resting state and is known as the transpulmonary pressure (P_L).

$$P_L = P_A - P_{pl} \qquad \textbf{Eq. 49.4}$$

Finally, the difference between the pleural space and atmospheric pressure outside

the chest wall (P_B, conventionally considered to be zero or reference) is a measure of the forces that the muscles have to surmount in order to force the chest wall (interestingly, including the muscles themselves) to increase or decrease its volume to accommodate the inflation and deflation of the lungs:

$$P_W = P_{pl} - P_B \qquad \textbf{Eq. 49.5}$$

For the sake of simplicity, we will consider first the particular situation in which the lungs undergo passive distention without participation of the respiratory muscles. This is what happens during positive airway pressure ventilation, when the pressure drive for inflation of the whole thorax is provided by the gradient ($P_M - P_B$). By performing a series of substitutions in Eqs. 3 through 5 and assuming $P_B = 0$, we can easily arrive at the following equality:

$$P_M = P_{AW} + P_L + P_W \qquad \textbf{Eq. 49.6}$$

This formula informs us that, from a mechanical point of view, the airways, lungs, and chest wall are arranged *in series,* and thus the total pressure needed to generate a movement is the sum of the pressures generated by each of these three components. Respiratory physiologists have often borrowed from electrical theory, assuming, perhaps to the dismay of many readers, that the simplicity of electrical circuitry is less intimidating than the complexities of Newtonian mechanics. When speaking of electrical circuits, the term *series* indicates that every element in the circuit experiences the same current as the circuit as a whole, but the total voltage across the circuit is the sum of the voltages across the individual elements. Because current is the electrical analog of flow (volume per unit of time) and voltage is the analog of pressure, it is easy to see how Eqs. 2 and 6 justify the electrical analogy.

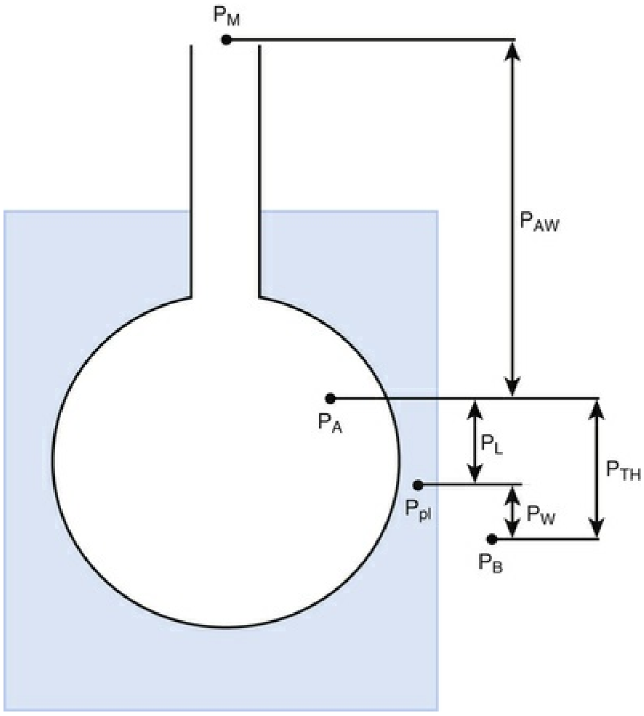

FIG. 49.2 Schematic representation of the thorax demonstrating the relevant pressure gradients generated during breathing. The difference (P_{AW}) between the pressure at the mouth (P_M) and the pressure at the alveoli (P_A) drives gas flow back and forth between the atmosphere and the alveolar spaces. The transpulmonary pressure (P_L) is the pressure that distends the lungs and is calculated as the difference between P_A and pleural pressure (P_{pl}). The transmural pressure of the chest wall (P_W) is the effective pressure distending the rib cage and abdomen and is defined as the difference between P_{pl} and atmospheric pressure (P_B).

The mechanical behavior of the airways and lungs does not change substantially during muscle-powered breathing. The behavior of the chest wall, on the other hand, is greatly influenced by the contraction of the respiratory muscles. Because the muscles are part of the chest wall and change their mechanical characteristics as they contract, any attempt to define mathematically the behavior of the chest wall during a spontaneous breath is a futile exercise. For our purposes here, however, it may suffice to say that, during spontaneous breathing, Eq. 6 may be written as:

$$P_{mus} = P_{AW} + P_L + P_W \qquad \textbf{Eq. 49.7}$$

where P_{mus} represents the pressure generated by the muscles' contraction. Thus every time we take a breath, the neural output to the respiratory muscles is adjusted to overcome as precisely as possible the opposing pressures generated by the respiratory system.

Nature of the Mechanical Forces Acting on the Respiratory Pump

Volume changes within the respiratory system are dictated primarily by the body's

need to take up oxygen and eliminate carbon dioxide and therefore are determined by factors such as physical activity or metabolic rate, which are relatively independent of the condition of the lungs and chest wall. Pressure changes, on the other hand, depend on the complex physical processes that take place in the respiratory system's constituents as they undergo motion. For instance, elastic pressures result primarily from the tendency of tissue components such as collagen and elastin fibers to recover their original shape after being stretched during lung inflation, but they also include pressures generated by surface tension at the alveolar gas-liquid interface. Airway resistive pressures relate to friction and overcome the adherence of the moving gas molecules to the airway walls (viscous pressures) and, to a lesser extent, compensate for the loss in gas kinetic energy at points where the movement and direction of the gas change rapidly. Tissue-resistive pressures are applied primarily to produce molecular rearrangements in the tissue and at the gas/liquid alveolar interface as the lungs inflate and deflate. Finally, inertial pressures derive from the acceleration and deceleration of the gas and tissue contained in the thorax during breathing. (Inertial pressure losses are negligible in children during normal breathing and therefore deserve no more than a passing reference here.)

Disease alters these physical processes and therefore also influences the forces and pressures that result from them. To relate these alterations to the disease's clinical manifestations, it is helpful to classify both processes and pressures into nondissipative and dissipative, depending on whether the potential energy used by the respiratory muscles to produce movement stays in or leaves the system. For instance, elasticity is typically a nondissipative process because the energy needed to produce elastic deformation during inspiration is accumulated in the tissues and then used to empty the lungs during expiration; it never leaves the system. In contrast, all resistive processes are dissipative: The energy liberated by the friction of the gas against the airway walls or by the molecular interactions within the tissue is transformed into heat, which is then transported outside of the system (dissipated) by the blood or the expired gas.

Nondissipative Phenomena: Elastic Behavior of the Respiratory System

Elastic pressures result from the tendency of the components of the lungs and chest wall to recover their original shape after undergoing deformation. Because this tendency increases proportionally to the magnitude of the deformation, elastic pressures are volume dependent. Thus they are most easily studied when the volume of the thorax is kept constant, a situation in which the absence of movement renders all resistive pressures irrelevant. This can be accomplished by inflating the lungs passively to the desired level (as in a breath hold) or by asking the subject to inspire to a given volume and then close the glottis while relaxing the respiratory muscles (something that a trained individual can do). In such circumstances, $P_{AW} = 0$, and therefore:

$$P_A = P_L + P_W \quad \textbf{Eq. 49.8}$$

By obtaining measurements at various volumes and then plotting volume against P_A, P_L, and P_W (remember our walk!), we can compare the volume-pressure relationships of the thorax as a whole with those of the lungs and the chest wall (Fig. 49.3). Not unexpectedly given the heterogeneous composition of the structures involved, the relationships are complex and cannot be described in a simple mathematic equation. In all three cases, the plotted curve has a sigmoid shape, with pressure increasing rapidly relative to volume at low and high volumes and more slowly at middle volumes.[1]

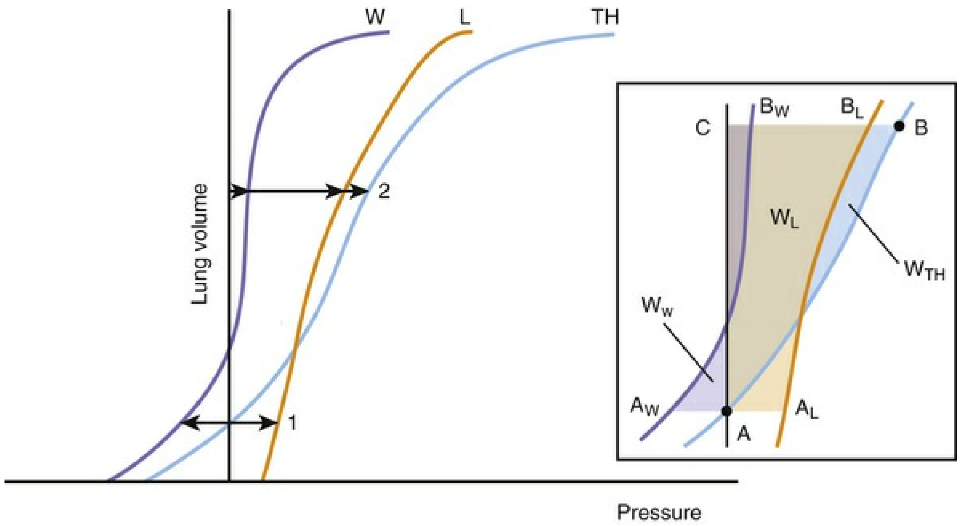

FIG. 49.3 Idealized representation of the static volume-pressure relationships of the thorax *(TH)*, lungs *(L)*, and chest wall *(W)*. Pressure, on the abscissa, represents the pressure across the thorax as a whole ($P_{TH} = P_A - P_B$), lungs ($P_L = P_A - P_L$), and chest wall ($P_W = P_{pl} - P_B$; see Fig. 49.2). The *arrows* indicate the magnitude and direction of the pressures acting on the thorax and its components at two volumes: (1) the relaxation volume of the thorax, where the recoils of the lung and the chest wall neutralize each other; and (2) an arbitrary volume where the recoils of the lungs and the chest wall act both in the direction of reducing thoracic volume. *Inset:* Detail of the same curves, indicating the elastic work done on the thorax as a whole and each of its components for a volume displacement starting at a volume *A* (the relaxation volume of the thorax) and ending at a volume *C*. The work done on the thorax as a whole is represented by the area *A-B-C;* the work done on the lungs by A-A_L-B_L-C; and the work done on the chest wall by A_W-A-B_W-C. A portion of the work done on the chest wall (the *triangular area in purple* between A_W and the ordinate axis) is contributed by the recoil of the chest wall, which between those points facilitates the action of the respiratory muscles.

Being a continuous function, each volume-pressure relationship has a defined slope at any given volume (dV/dP). This slope defines the *compliance* of the thorax, lungs, or chest wall for that particular volume, depending on whether dP is replaced by dP_A, dP_L, or dP_W. Although a cursory examination of Fig. 49.3 reveals that both the lung and chest wall compliances defined in this manner vary markedly over the

entire range of volumes, on closer inspection, the ratio dV/dP is relatively constant at normal breathing volumes. Thus for these volumes, it is safe to write:

$$\Delta P_{el} = \Delta V / C \qquad \textbf{Eq. 49.9}$$

where ΔP_{el} represents the change in elastic recoil pressure of the thorax (ΔP_A), lungs (ΔP_L), or chest wall (ΔP_W) for a lung volume excursion ΔV, and *C* is the compliance of the corresponding component. As lung volume decreases or increases beyond this linear range, dV/dP starts to decrease in a volume-dependent manner and the respiratory muscles must generate progressively larger pressures to produce the same volume change. Disease frequently causes the lungs to operate on the fringes of the volume-pressure range, thereby increasing rapidly both the work of breathing and the energy needed to do it.

At any given volume, the lungs, chest wall, and thorax each generate a certain elastic pressure or recoil. This recoil can act to increase or decrease volume (as indicated by the direction of the *arrows* in Fig. 49.4). By definition, elastic recoil drives the thorax and its individual components to adopt a volume, known as the *relaxation volume,* at which recoil itself is extinguished. The relaxation volumes of the lungs and the chest wall are the volumes that each of these components would adopt if all the mechanical constraints imposed by their mutual attachments and interactions were removed. The relaxation volume of the thorax, in contrast, is defined by the mechanical interaction of the lungs and the chest wall. It coincides with the point at which the opposing elastic recoils of these two components neutralize each other (as shown by the equal magnitude but opposite pressure vectors at the points labeled 1 in Fig. 49.4).

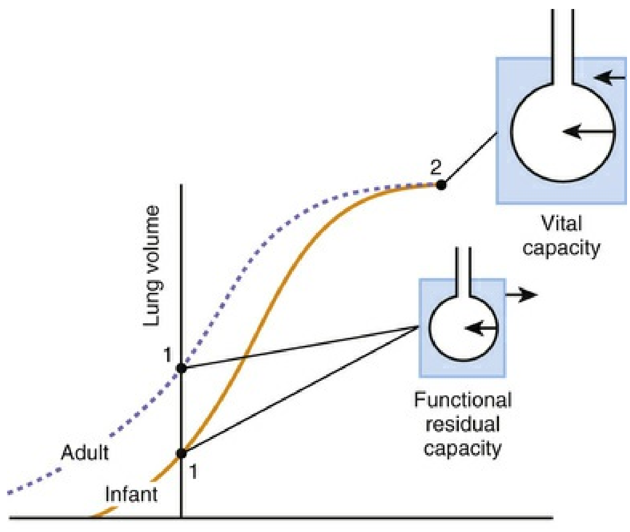

FIG. 49.4 Idealized volume-pressure relationships illustrating the differences in the elastic behaviors of the infant and adult thoraxes (normalized for vital capacity). The difference between the two points (labeled *1*) highlights the effect of maturation on the relaxation volume of the thorax. In the infant the chest wall is considerably more compliant than in the adult and, as a result, the opposite recoils of the lungs and the

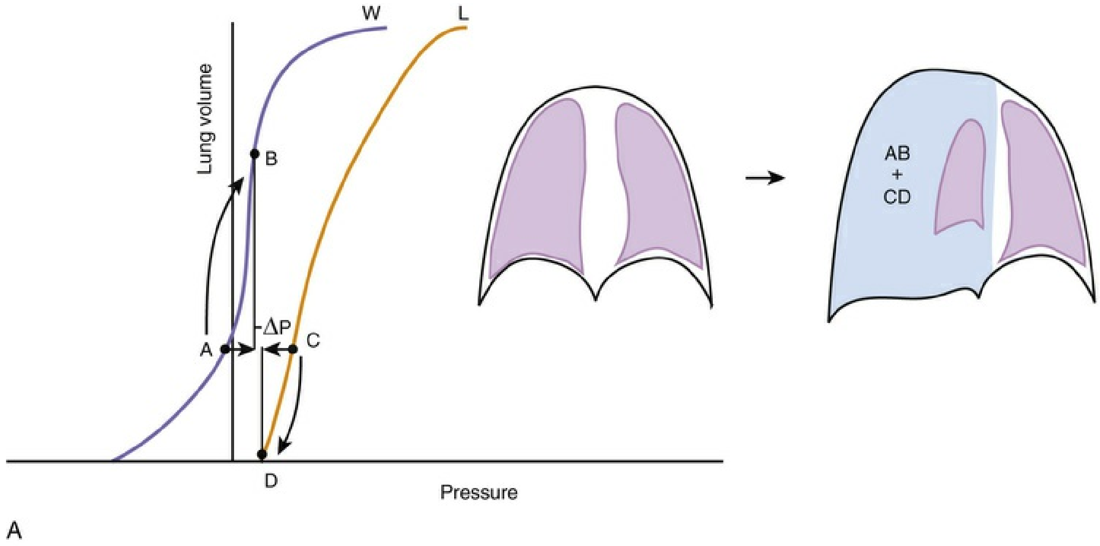
chest wall neutralize each other at a lower relaxation volume. Thus infants have a lower functional residual capacity *(FRC)* than do adults. At volumes higher than the relaxation volume of the chest wall, the recoils of the lungs and chest wall act in the same direction, opposing further increases in volume (as highlighted here at vital capacity, labeled *2*).

In the adult, at relaxation volume, the gas contained in the lungs is less than the residual volume (the volume of gas contained in the lungs at the end of a forced expiration). The relaxation volume of the chest wall, by contrast, exceeds 50% of the volume at vital capacity (the maximal volume of gas that can be inhaled from residual volume). This discrepancy in the relaxation volumes of the lungs and chest wall has three important consequences. First, it forces the relaxation volume of the thorax as a whole to occupy a position intermediate between the relaxation volumes of the lungs and the chest wall (at approximately 35% of vital capacity). Under most circumstances, this volume coincides with the functional residual capacity (FRC), which is the volume contained in the lungs at the end of a tidal expiration at steady state. Second, as the thorax starts to rise above its relaxation volume during inspiration, the outward recoil of the chest wall contributes to the expansion of the lungs, thereby reducing the work that the respiratory muscles need to perform during normal breathing (see Fig. 49.3, *inset,* where the work done by the chest wall at the beginning of a breath is labeled W_W). Finally, at normal breathing volumes, the opposing actions of the lungs and chest wall recoils create a negative pressure at the boundaries of the lung tissue with the chest wall and other intrathoracic structures. This negative pressure is an important contributor to the return of venous blood to the chest. The static volume-pressure relationships of the lungs and chest wall vary depending on their state of maturation and health (see Fig. 49.4). In the infant, the chest wall generates remarkably little outward recoil within the normal range of breathing volumes.[2-4] Because the inward recoil of the lungs varies little with respect to lung size and age during development,[5,6] the relaxation volume of the infant's thorax is proportionally smaller than that of the adult (as shown in Fig. 49.4 by the lower intercept of the volume-pressure relationship of the thorax and the ordinate axis). If, as occurs in the adult, the FRC coincided with this relaxation volume (15% of vital capacity compared with 35% in the adult), then the infant would be at a definite disadvantage in terms of alveolar stability and oxygenation. The newborns of most mammalian species, however, have developed physiologic strategies to maintain their FRC above the relaxation volume of the thorax.[7] These strategies, which may be even more important in the presence of respiratory illness,[8] are generally directed at interrupting expiratory flow before expiration is complete and include shortening of the expiratory time,[9] contraction of adductor muscles of the glottis to retard exhalation,[10] and persistence of the tonic activity of the inspiratory muscles during expiration.[11] Being so dependent on the pattern of breathing, the FRC of the newborn and small infant is vulnerable to changes in muscle coordination and tone. As an example, the decrease of tonic activity of the respiratory and laryngeal muscles associated with rapid eye movement sleep[11] may cause a substantial reduction in thoracic lung volume at these ages. Similarly, muscle weakness, anesthesia, deep sedation, and central nervous system depression in general tend to lower FRC below levels compatible with alveolar stability. Under such circumstances, alveoli close and both the shunt fraction and work of breathing increase.

In addition to its effects on the FRC, the reduced outward recoil of the chest wall in the infant reduces the chest wall's contribution to lung expansion. It also limits the amplitude of the pleural pressure variations as the lungs expand, an effect that helps to explain the surprising cardiovascular tolerance of many infants to the application of high levels of positive airway pressure.

Lungs/Chest Wall Interactions

Although, considered in isolation, the lungs and chest wall have different volume-pressure relationships, their mechanical linkage at the pleural space prevents them from changing volume independently. By sharing a common boundary, the lungs and chest wall are also influenced simultaneously by variations in the pressure at this boundary. The resultant interplay is well illustrated by the effects of a pneumothorax, a complication that is quite familiar to readers who practice intensive care medicine. When a certain volume of gas enters the pleural space, the most immediate effect is an increase in pleural pressure (ΔP). This increase causes the effective transmural pressures of the lungs and chest wall to change by the same absolute amount but in opposite direction: transpulmonary pressure ($P_A - P_{pl}$) decreases by −ΔP, whereas chest wall transmural pressure (P_{pl}) increases by ΔP. No longer held together by a rigid boundary, the lungs and chest wall respond to the change in transmural pressure by decreasing and increasing volume along their respective volume-pressure relationships (Fig. 49.5A). Consequently, one could say that the volume of air originally introduced in the pleural cavity is partitioned into two components, one corresponding to the volume lost by the lungs as they collapse and the other corresponding to the volume gained by the chest wall as it expands. The relative extents to which the lungs collapse and the chest wall expands are dictated by the volume-pressure relationships of the lungs and chest wall. If the compliance of the chest wall exceeds the compliance of the lungs (as is usually the case in the infant), then the chest wall expands more than the lungs collapse. The difference is even greater when lung compliance is reduced by disease (Fig. 49.5B). Then the chest wall absorbs the majority of the volume change while the lungs barely decrease their volume. This simple analysis explains why noncompliant lungs show surprisingly little collapse when a pneumothorax develops, a finding that is often mistakenly attributed to the "stiffness" of the lung parenchyma. It also provides an opportunity to point out that the magnitude of the chest wall expansion, although frequently overlooked when a pneumothorax is diagnosed radiographically, relates more directly to the true malignancy of the process (the impediment of cardiac filling by the compression of the intrathoracic vessels) than does the usually more apparent collapse of the lungs.



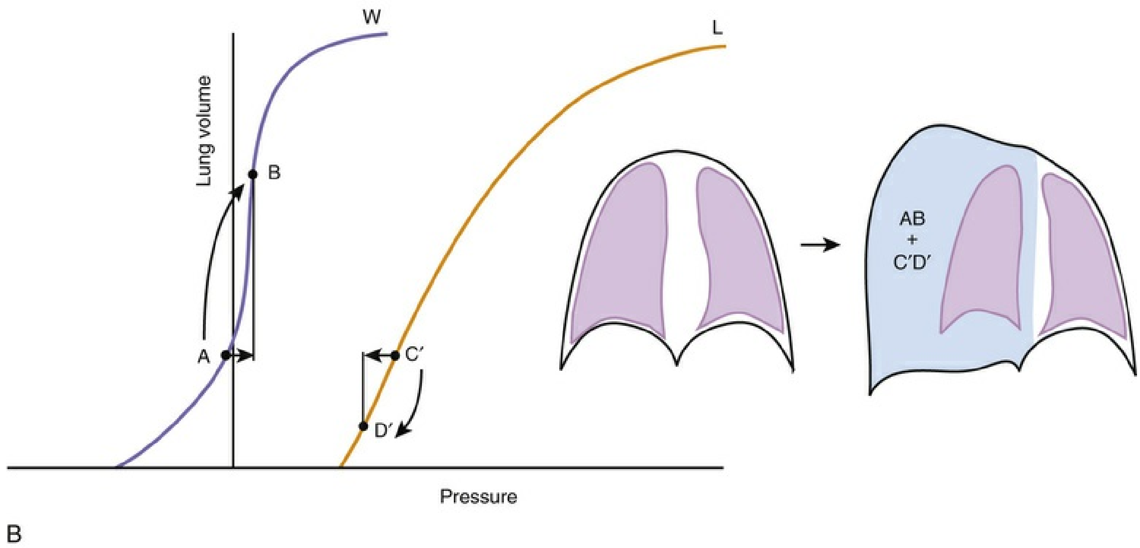


FIG. 49.5 (A) The effects of a pneumothorax are used here to illustrate the interactions between the elastic recoils of the lungs and the chest wall. Pressures, on the abscissa, represent the transmural pressures of the lungs (*L*, $P_A - P_{pl}$, see Figs. 49.2 and 49.3) and chest wall (*W*, $P_{pl} - P_B$). The introduction of a volume of gas into the pleural space raises pleural pressure by a magnitude ΔP, which changes both transmural pressures by the same absolute magnitude but in opposite directions. Lungs and chest wall respond to the change in transmural pressure by decreasing *(C→D)* and increasing their volume *(A→B)* along their respective volume-pressure relationships. The volume of the pneumothorax is thus partitioned between the lungs and the chest wall according to their relative compliances. (B) When lung compliance is decreased by disease, the volume-pressure relationship of the lungs is displaced to the right and has a lower slope (or compliance). Under these circumstances, the chest wall is forced to accommodate the majority of the volume change introduced by the pneumothorax *(AB ≫ C′D′)*, giving perhaps the wrong impression that the stiffness of the lungs prevents them from collapsing further.

One important idea to emerge from these considerations is that, respiratory

muscle activity aside, the pressure inside the pleural space is really determined by the elastic recoil of the chest wall and volume of the thoracic contents. As long as lung volume is not forced above its normal range and chest wall compliance is unaltered by disease, pleural pressure (and thus the pressure around the major vessels and the heart) remains low, regardless of the airway pressures. Conversely, excessive lung distension (eg, in asthma or other conditions in which the lungs are overinflated) is always associated with a high pleural pressure and is, for that reason, less well tolerated from a cardiovascular point of view. The dependence of pleural pressure on chest wall compliance explains why premature infants and newborns, who have very large chest wall compliance, have limited changes in this pressure during positive pressure ventilation, even if physiologic lung volumes are exceeded. Disease-induced reductions in chest wall compliance, on the other hand, always increase pleural pressure and reduce venous return to the heart. This is one reason why patients with abdominal distension typically have low cardiac output and why relief of the distension (eg, by paracentesis in patients with ascites) reduces pleural pressure and increases cardiac output.

Dissipative Phenomena: Resistive Behavior of the Respiratory System

Dynamic Volume-Pressure Relationships

Analysis of the volume-pressure relationships of the thorax and its components becomes more complicated when we consider the pressure changes generated by gas flow and movement of the lung and chest wall tissue as the lungs inflate and deflate. These pressure changes result from molecular interactions between the gas and airway walls, within the gas stream itself, and among the components of the gas-liquid interface and tissue. The same interactions are responsible for well-known physical phenomena such as viscosity (the internal resistance of a fluid to flow), turbulence (the development of chaotic, energy-consuming movements within a flowing fluid), or viscoelasticity (a property of tissues and fluids that causes their deformations to be time dependent; ketchup provides a good example when it hangs stubbornly to the bottle before being released after multiple taps).[12-14]

Regardless of their ultimate physical nature, all the phenomena that occupy our attention at this point have two characteristics in common. The first is that they always result in a net loss or dissipation of energy from the respiratory system. The lost energy can no longer be used to perform work, and consequently dissipative pressure losses cause the volume-pressure relationships of the respiratory system to follow a different trajectory depending on the direction of the volume change. This property, known as *hysteresis,* is responsible for the development of loops when the volume-pressure relationships are plotted continuously during a breath (Fig. 49.6). In this graphic representation, the dissipative pressures can be easily identified as the horizontal distance between the volume-pressure tracing and the corresponding point on the elastic volume-pressure relationship. The work done against these pressures can be quantified as the area enclosed by the loop.

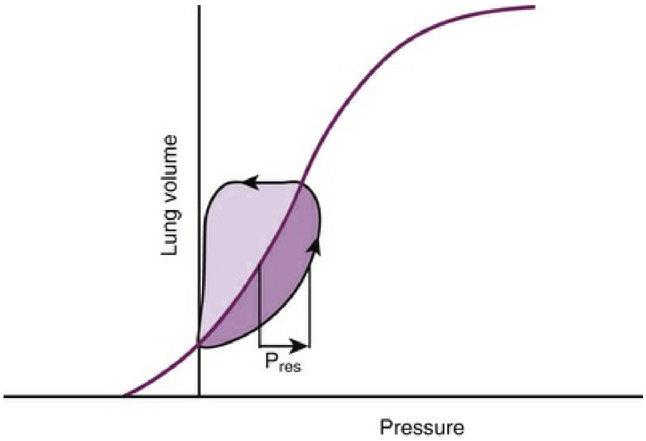

FIG. 49.6 Idealized representation of the dynamic or real-time volume-pressure relationship of the respiratory system during a single breath (the *arrows* indicate the direction of the movement). Because energy is dissipated as the lungs change volume, the relationship follows a different trajectory during inspiration and expiration, forming a loop (hysteresis). The horizontal distance between any point in the loop and the line describing the elastic volume-pressure relationship of the respiratory system *(black)* is the pressure needed to overcome the dissipative forces present at that point in the breath *(P_{res})*. The area enclosed by the loop *(shaded area)* is the amount of energy used in overcoming these forces. The inspiratory portion of this work (*darker shading* between the loop and the elastic volume-pressure relationship) must be performed by the respiratory muscles. The expiratory portion of the work *(lighter shading)* is normally done by the elastic recoil of the lungs and chest wall and requires no muscle effort or energy consumption. The resistance of the respiratory system is calculated by dividing P_{res} by the airway flow.

The second common characteristic of dissipative pressures losses is that they occur only when there is volume change or flow in or out of the lungs (flow is the first derivative of volume with respect to time, dV/dt, and is usually represented with the engineering symbol $\dot{V}$. The relationship between resistive pressure loss (P_{res}) and $\dot{V}$ is, under most circumstances, simple enough to be summarized with a linear equation:

$$P_{res} = R \cdot \dot{V} \qquad \textbf{Eq. 49.10}$$

where the coefficient *R* defines the flow resistance of the corresponding component (thorax, lungs, or chest wall). While the concept of resistance is useful as a pulmonary function assessment and reporting tool, the idea of assigning a fixed value to R involves a gross oversimplification. Indeed, resistive pressure losses are influenced by factors other than the absolute flow rate, including among others lung volume, flow direction (inspiratory or expiratory), and breathing pattern. An understanding of the role played by these factors during normal breathing provides valuable insights for the recognition and treatment of airway obstruction.

Effect of Flow Rate and Pattern on the Dynamics of the

Gas Stream

The airway tree is a complex fractal-like structure. A particle traveling in the gas stream from the mouth to the alveolus would likely encounter obstacles and bifurcations and experience periods of acceleration and deceleration along the way. Thus in real life, the pressure losses, and thus the amount of work that needs to be done to sustain these losses, are a complex function of flow and geometry. In the simplest of circumstances, a tube with a uniform diameter, gas flow tends to adopt a *laminar* arrangement with a *parabolic velocity profile,* whereby the gas molecules in the middle move faster than the ones near the wall, which are slowed down by their viscous interaction with the wall (in fact, the molecules next to the wall may not move at all). Under these circumstances, energy dissipation is minimal and the pressure loss in the tube can be estimated with Pouiselle's law:

$$P_{res} = \frac{128 \cdot \mu \cdot L}{\pi \cdot d^4} \times \dot{V} \qquad \textbf{Eq. 49.11}$$

where μ is the viscosity of the gas, L the length of the tube, and d its diameter. It is easy to see that the complex fraction on the right side of this equation corresponds to the coefficient R in Eq. 10.

Considerable theoretic and empiric evidence exists that although laminar flow is common, Pouiselle flow conditions are rare in the airways. The reason for this phenomenon is that airway segments are generally too short to allow the development of velocity differences between layers and thus the establishment of a parabolic profile. The resultant blunt velocity profile (ie, the molecules move at similar speed in the center lines as in the vicinity of the airway wall) results in greater friction and causes the relationship between P_{res} and $\dot{V}$ to become nonlinear. Or, put in a different way, the value of R becomes dependent on $\dot{V}$.

The dependence of R on $\dot{V}$ becomes even more pronounced when an obstacle disturbs the laminar organization of the flow stream. Under these circumstances, the velocity and direction of the gas molecules can vary vigorously and randomly and a turbulent flow pattern is created. When flow becomes turbulent, energy dissipation increases exponentially with flow rate and the density of the gas becomes more relevant than its viscosity in determining both pressure losses and work. This is the reason why helium, which has a much lower density than air, can decrease the work of breathing substantially in patients with some forms of airway obstruction (even though its viscosity is slightly greater than the viscosity of air).

Airway Dynamics

The airways provide a distribution network to transport gas to and from the gas-exchanging units of the lungs. Although often idealized as a system of passive pipes, the airway network is in reality a highly specialized organ. Each airway segment, from the nose to the alveoli, has evolved to not only serve specific functions such as humidification and phonation but also ensure maximal patency under the changing mechanical conditions present during breathing.

Indeed, the activity of the respiratory muscles exposes the airways to considerable

transmural stresses (or pressures) during breathing (Fig. 49.7). The caliber and length of the airways change in response to these stresses in a manner that is only limited by the passive rigidity of its wall tissues and by the tone of the airway intrinsic muscle. Thus airway transmural pressure (the difference between the pressures measured on the inside and outside surfaces of the airway wall) and airway wall compliance (defined both as compressibility and distensibility) are the two determinants of airway caliber and, ultimately, also the determinants of airway resistance.

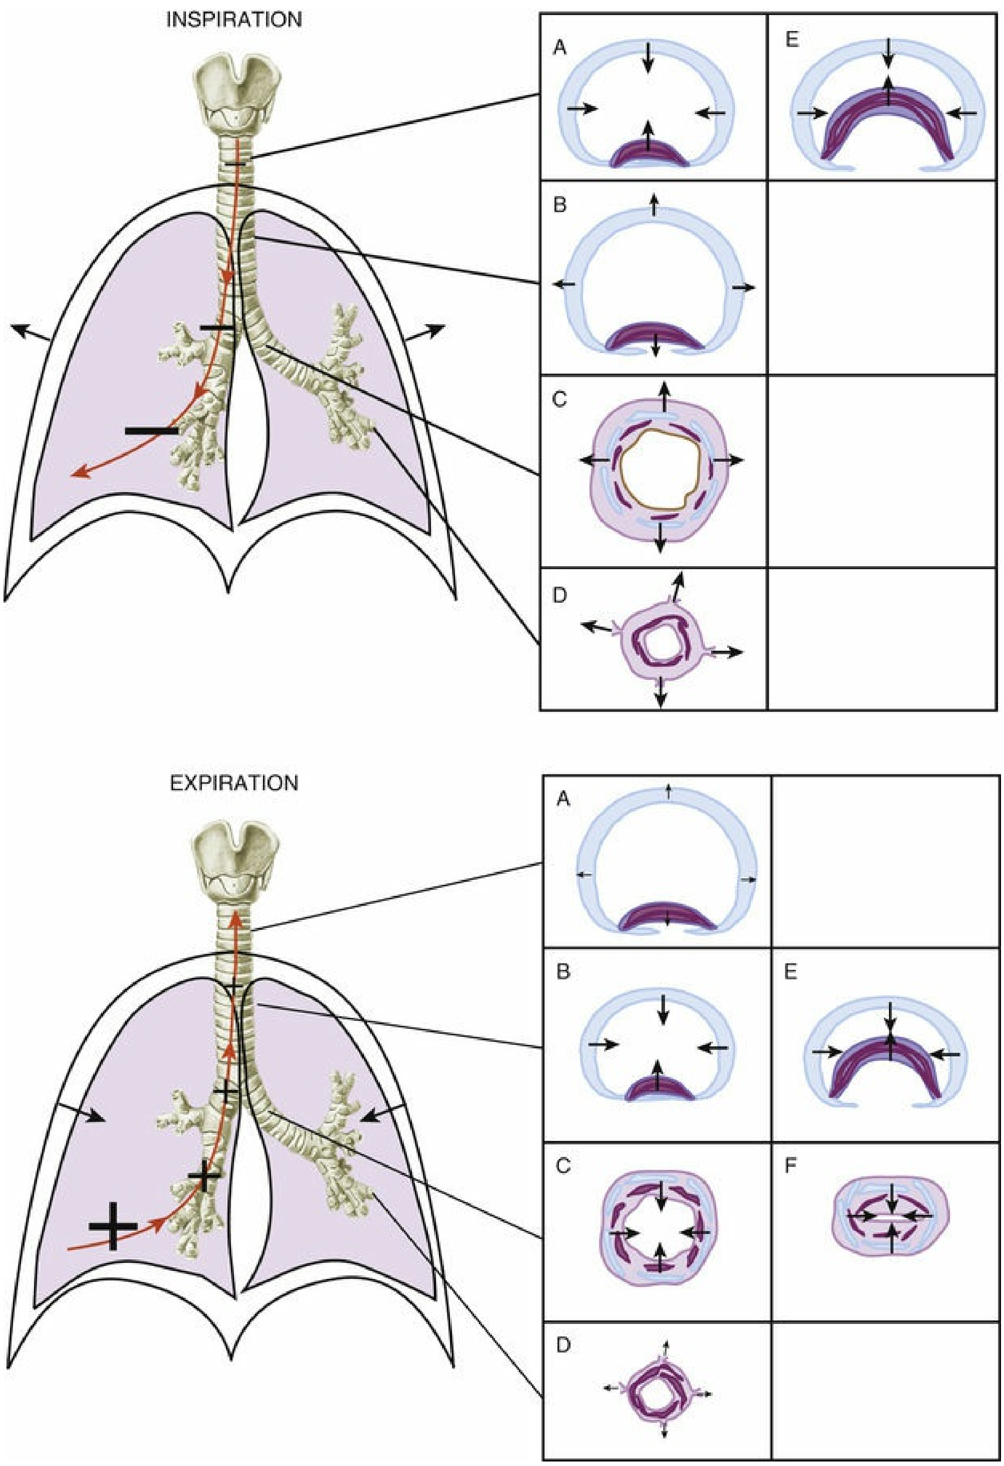

FIG. 49.7 Schematic representation of the differential effects of inspiration and expiration on the configuration of the extrathoracic and intrathoracic airways. During inspiration, the contraction of the respiratory muscles creates a negative pressure (relative to atmospheric) in the alveoli. This pressure drives inspiratory flow and, depending on the flow itself and the resistance of the airways, results in progressively less negative—but negative nonetheless—pressures in the direction of the mouth (as shown by the progressively smaller size of the negative signs in the picture). During expiration, the recoil of the thorax (and, at times, the contraction of the expiratory muscles) reverses the situation, and pressures are more positive in the alveoli than in the more proximal airways. The caliber of the airways is determined by the difference between airway pressure and the pressure acting on the outside surface of their walls (airway transmural pressure). The latter approximates atmospheric pressure (zero reference) for the extrathoracic airways and pleural pressure for the intrathoracic airways. Thus during inspiration, airway transmural pressure (which is represented in magnitude and direction by the *arrows*) acts to decrease the caliber of the extrathoracic airways (represented here by the extrathoracic portion of the trachea, *A*) and to increase the caliber of the intrathoracic trachea *(B),* large bronchi *(C),* and bronchioles *(D).* Note that, in the case of the bronchioles and other intrapulmonary airways, the relevant pressure outside the airways is transmitted to the airway wall by the tissue elements that tether them to the surrounding tissues in the lung. During expiration, the phenomenon is reversed, and, although the transmural pressure is positive in the distal portions of the airway tree, it decreases progressively and may eventually become negative (as shown in the example by the inward-directed *arrows* in *C*). Abnormalities in the tone of the airway muscle or the stiffness of the airway cartilage exaggerate these effects and promote collapse of the extrathoracic airways during inspiration (shown here for the trachea, *E*) and the intrathoracic airways during expiration (*E* and *F*).

Airway transmural pressure varies during breathing. Its variations result from the fact that inspiration and expiration have very different effects on the pressures inside and outside the airways. The pressure inside all airways undergoes qualitatively similar changes during each phase of the breathing cycle. During inspiration, for instance, there is a gradient of increasingly negative pressures from the mouth, where pressure is atmospheric (or the zero reference), to the alveolar spaces, where the pressure must be negative (or subatmospheric) for gas to flow in. This negative pressure is of course driven by the actions of the respiratory muscles and transmitted to the lungs via the link between the chest wall and lungs at the pleural space. During expiration, alveolar pressure becomes positive and the gradient is inverted, with the pressures inside the airways being always positive but diminishing toward the mouth.

The pressure outside the airways is influenced in a different fashion by inspiration or expiration depending on whether the airways are extrathoracic or intrathoracic. Extrathoracic airways are included in the tissues of the neck, where the pressure can be considered to be atmospheric (at least in nonobese individuals, in whom tissue gravitational forces are neutralized by the skeletal support of the neck). Most of the intrathoracic airways are embedded in the lung tissue, where multiple tethering elements transmit the stresses (or pressures) generated by the tissue recoil to the airway wall (a phenomenon known as *pulmonary interdependence*[15]). Therefore the

pressure outside the intrapulmonary airways approximates the pleural pressure and, as we have seen, relates to lung volume in a manner that depends on the pressure-volume characteristics of the chest wall (see the section on Lungs/Chest Wall Interactions).

Taking these considerations altogether, it follows that the effect of inspiration and expiration on airway caliber is very different depending on whether the airway is outside or inside the chest cavity. During inspiration, the extrathoracic airways (ie, the pharynx, larynx, and extrathoracic portion of the trachea) become narrower because the pressure inside their lumen decreases while the pressure immediately outside their walls is constant (pulling the airway wall in, as shown by the direction of the arrows acting on the wall of the trachea in Fig. 49.7, *top panel A*). The intrathoracic airways, however, become dilated because the pressure outside their walls (the pleural pressure) decreases more than the pressure inside their lumen (see Fig. 49.7, *top panel B, C,* and *D*). Conversely, during expiration the extrathoracic airways increase their caliber as their inside pressure becomes positive with respect to atmospheric pressure (pushing the wall out, as also shown by the direction of the arrows in Fig. 49.7, *bottom panel A*) and the intrathoracic airways narrow as their inside pressure decreases with respect to pleural pressure (see Fig. 49.7, *bottom panel B, C,* and *D*).

It is important to understand that the narrowing of the intrathoracic airways during expiration is contingent on the existence of a pressure gradient from the alveoli to the mouth. As predicted by Eq. 4, alveolar pressure (P_A) must always exceed pleural pressure (P_{pl}) by a magnitude equivalent to the elastic recoil of the lungs. As the gas progresses downstream during expiration, frictional pressure losses lower the pressure inside the airways. Eventually the cumulative pressure losses can be as large as the pulmonary elastic recoil, and the pressure inside the airways becomes equal to P_{pl}. Beyond this *equal pressure point* (somewhere between the points depicted in *bottom panels D* and *C*), airway transmural pressure becomes negative (ie, the pressure outside exceeds the pressure inside the airway) and acts to collapse the airway. The resultant interplay between the negative transmural pressure and compliance of the airway wall can give rise to a condition known as *flow limitation,*[16,17] whereby gas flow can no longer increase even if the subject makes a greater expiratory effort to raise alveolar pressure. Because the majority of the dissipative pressure losses are related to gas viscosity, this type of flow limitation is known as *viscous* flow limitation (Fig. 49.8).

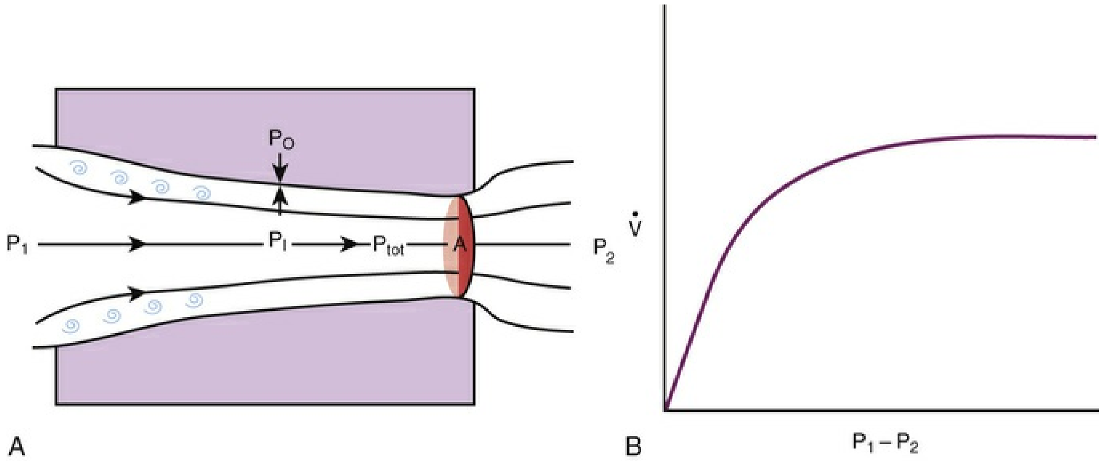

FIG. 49.8 (A) Flow limitation develops when the transmural pressure $(P_I - P_O)$ of a collapsible tube (such as an airway) and the flow in the tube interact in such a manner that the cross-section of the tube (A) cannot support an increase in the flow rate, independent of the pressure driving the flow $(P_1 - P_2)$. Viscous flow limitation occurs when viscous friction (illustrated by the eddies at the edge of the flow stream) causes the pressure acting on the inner surface of the tube wall (P_I) to decrease faster than can be accommodated at any given flow. Wave-speed flow limitation takes place when the increase in the kinetic energy of the fluid or gas at a point of narrowing causes P_I to decrease relative to the head pressure (P_{tot} or the pressure that we would register with a probe facing the direction of flow) so that any further increase in flow cannot be supported by a further reduction in A. (B) Regardless of the mechanism, when flow is limited, any increase in the driving pressure (or, in the case of the airways, the effort of the respiratory muscles) cannot increase flow $\dot{V}$.

Flow limitation is an important concept that is pertinent to many clinical situations in which flow is both decreased and effort independent. It occurs in subjects with asthma and other forms of intrathoracic airway obstruction[18,19] when the increased effort to exhale does not accelerate lung emptying and is therefore wasted. It also occurs in persons with croup and other forms of extrathoracic airway obstruction when the increased effort to inhale cannot increase inspiratory flow, and the attempt only succeeds in creating more stridor and respiratory muscle fatigue. However, it is important to point out that not all situations of flow limitation relate to dissipative pressure losses. For more than 30 years we have known that flow in a compliant tube, such as an airway, cannot exceed the minimum flow at which the velocity of a particle suspended in the flow equals the local wave-speed for the tube. The wave-speed is the velocity at which a disturbance travels through the tube, a concept that is familiar to clinicians because the wave-speed is the velocity at which the pulse waveform travels through arteries. Wave-speed flow limitation ultimately results from the coupling of airway compliance and convective acceleration (see Fig. 49.8). As the respiratory gas moves through areas of decreasing cross-section, the kinetic energy of the gas increases at the expense of the total energy contained in the flow stream. As a result, there is a decrease in the pressure acting on the inner surface of the airway (this decrease is the basis for the Venturi effect) and the transmural pressure of the airway decreases. Once again, if the airway is sufficiently compliant,

there is a maximum flow beyond which the inside pressure would decrease faster than can be accommodated by the decrease in cross-sectional area and flow becomes limited. Regardless of its causal mechanism (viscous or wave-speed), flow limitation occurs at lower flows in the presence of airway obstruction and at low lung volumes, when airway diameter is minimal.

Airway Muscle and Compliance of the Airways

The effect of transmural pressure on the caliber of an airway depends on the mechanical characteristics of the airway itself or, more specifically, on its ability to undergo collapse or distension, a property that is often described as airway wall compliance. The structure of each segment of the airway tree has evolved to minimize luminal distortion in response to the varying stresses that act on the airway wall during breathing. The pharynx and larynx, for example, contain skeletal muscle, which stiffens their walls or dilates the pharyngeal lumen and the glottis during inspiration under the control of cranial nerves IX and X. Loss of pharyngeal or laryngeal tone during sleep or after pharmacologic inhibition or injury of the controlling neurons is the most important cause of upper airway obstruction during inspiration.

The smooth muscle of the trachea and bronchi has a similar function. For instance, the trachea is composed of a series of incomplete cartilaginous rings forming a relatively rigid arrangement that resists the collapsing effects of positive intrathoracic pressures during expiration. The rings leave a dorsal gap, where the wall of the trachea is soft. This weak point is bridged by the trachealis muscle, which, upon contracting, can approximate the edges of the cartilage rings and prevent the soft portion of the wall from bulging into the airway lumen (see Fig. 49.7). Like the smooth muscle in other airway segments, the trachealis muscle is innervated by local parasympathetic ganglia. The ganglia in turn receive inputs from parasympathetic preganglionic neurons located in the medulla via nerve fibers carried by the vagus nerves.[20,21] The medullary preganglionic neurons are anatomically and functionally integrated in the control of breathing. As a result, the traffic of impulses reaching the airway ganglia (and thus the tone of the muscle) varies with the phase of the breathing cycle and increases when the respiratory drive is increased, such as during exercise, hypercapnia, or hypoxemia.[22,23] Malformations or physical or pharmacologic interventions that disrupt the trachealis muscle or its nerve supply lead to tracheal obstruction when the intrathoracic pressure increases during expiration or when the child cries or exhales forcefully. This form of tracheal obstruction is often diagnosed as tracheomalacia, even though no true softening of the tracheal cartilage occurs.

The bronchial smooth muscle is also innervated by the parasympathetic system.[24] In cartilaginous bronchi, the stiffening effect of the muscle contraction is augmented by the cartilage and prevents the bronchial lumen from collapsing when the transmural pressure decreases during expiration, coughing, or crying. In bronchioles, which in humans lack cartilage, contraction of the smooth muscle stiffens the airway walls as well. However, in these smaller airways, smooth muscle contraction may have a more important function of preventing excessive airway distension during inspiration, when the stressed transmitted to the airway wall may disrupt the delicate bronchiolar structure.

Airway Obstruction

Airway obstruction causes an exaggeration of the reciprocating changes in airway caliber that we have just described during normal breathing. Thus the clinical manifestations of the obstruction depend on its location (extrathoracic or intrathoracic) and direction of flow (inspiratory or expiratory). When the obstruction is extrathoracic (eg, as occurs with croup, glossoptosis, and tonsil or adenoid hypertrophy), during inspiration the respiratory muscles must create a more negative pressure inside the airway segment downstream from the obstruction to overcome the increased resistance. Therefore this segment of the airway tends to decrease its diameter even further, worsening the obstruction and producing a characteristic turbulent noise (inspiratory stridor) as gas accelerates through the narrowest point and induces vibrations in the airway mucosa. The obstruction is relieved during expiration because the pressure inside the airway segment becomes positive with respect to atmospheric pressure.

When the obstruction is intrathoracic (eg, as occurs with extrinsic compression of the trachea and bronchi, tracheobronchomalacia, and asthma), during inspiration the pressure inside the airways downstream from the obstruction becomes much lower than it would be under normal circumstances. However, no matter how low, the pressure inside the airways still must be less negative than the pleural pressure (Eqs. 3 and 4) because otherwise lung recoil ($P_A - P_{pl}$) would be negative, which is unimaginable. Thus during inspiration the transmural pressure of intrathoracic airways always remains positive. In contrast, during expiration the pressure inside the airway segment located between the obstruction and the thoracic outlet may become lower than pleural pressure at some point (see the section on Airway Dynamics). This situation, coupled with the Venturi effect created by the acceleration of flow at the obstructed segments, causes these airways to collapse and produce high-pitched vibrations (wheezing), expiratory delay, and dynamic hyperinflation (often referred to as *gas trapping*).

A Specific Case Study in Airway Mechanics: Mechanical Ventilation

The application of positive pressure in the airways changes the balance of pressures that determines airway caliber. When positive end-expiratory pressure (PEEP) is used, pressure inside the airways is offset in the positive direction (relative to atmospheric pressure) during the entire respiratory cycle. As a result, any portion of the extrathoracic airway that is not bypassed by an endotracheal tube (or the entire extrathoracic airway when mask ventilation is used) experiences a net increase in transmural pressure, which is the reason why continuous positive airway pressure (CPAP) is helpful in the management of extrathoracic obstruction. The pressure inside the intrathoracic airways also increases, but the increase is negated to some extent by the effects that PEEP has on lung inflation and therefore on elastic recoil and pleural pressure (remember the always important principle enunciated in Eq. 4). For this reason, the effects of PEEP in patients with intrathoracic airway obstruction and gas trapping are unpredictable.[25] Although PEEP is beneficial in some of these patients, in others, it increases lung volume,[26] interferes with cardiovascular function, and ultimately decreases oxygen delivery to the tissues.[27] These individual

variations may simply reflect differences in the mechanisms of dynamic hyperinflation or simply heterogeneity of lung disease.[28,29] In patients who have gas trapping without expiratory flow limitation, proximal airway pressures (and thus also PEEP) are transmitted faithfully to the alveoli. As a result, their lung hyperinflation worsens. By contrast, in patients who have both gas trapping and expiratory flow limitation, PEEP may not influence the pressures upstream of the flow-limiting point; therefore, alveolar pressure and lung volume may not increase as much, but the increase in the transmural pressure at the choking segment may be sufficient to reset the maximum (limited flow rate) at a higher level. Although PEEP is not recommended in every patient, its judicious use may be considered, under careful monitoring, to improve the mechanical function of the lungs of some selected infants and children with severe obstructive airway disease.

Determinants of Regional Gas Flow Distribution in the Lungs

From a mechanical perspective, the lungs form a parallel arrangement of acinary or multialveolar units, each supported by a conducting airway. The development of inequalities in the mechanical and gas-exchanging functions of these units is a fundamental factor in the manifestations of lung disease. To understand how mechanical inequality affects the distribution of ventilation in the lungs, it is essential to realize that the potential filling volume of any alveolar unit is determined by the unit's compliance. However, the actual filling volume during a breath depends on the rate at which the unit can fill relative to other units.[30] This rate is a function of the unit's compliance and resistance in a manner that is best defined by the product of these two variables, a constant with the dimension of time known as the time constant (represented by the Greek letter τ).

The mathematic formulations that describe the distribution of flow among units with different time constants can be complex. However, it is possible to make some basic predictions of how a certain flow pattern will influence the distribution of tidal volume among these units. Imagine a simplified lung composed of three units (Fig. 49.9), one with a normal compliance and resistance (normal τ), another with a low compliance and a normal resistance (short τ), and the third with a normal compliance and a high resistance (long τ). As long as the inspiratory time is sufficiently long to allow equilibration of alveolar pressures within the lungs, a decelerating inspiratory flow pattern (pressure-controlled ventilation) will inflate all three units proportionally to their compliances, thus favoring the two units with normal compliance. If the inspiratory time is shortened, however, gas is still flowing at the end of inspiration. This situation results in pressure and inflation inequalities among the units, with a disproportionate portion of the tidal volume being directed to units with a short time constant (once again proportionally to their compliance) and away from the unit supplied by an obstructed airway. The effect of such redistribution on gas exchange depends on the blood supply received by each type of unit and is therefore difficult to predict in diseased lungs. However, the astute clinician may derive some insight into the mechanism of a given patient's gas exchange abnormalities by observing carefully the changes induced by variations in the flow rate and duration of inspiration during mechanical ventilation.

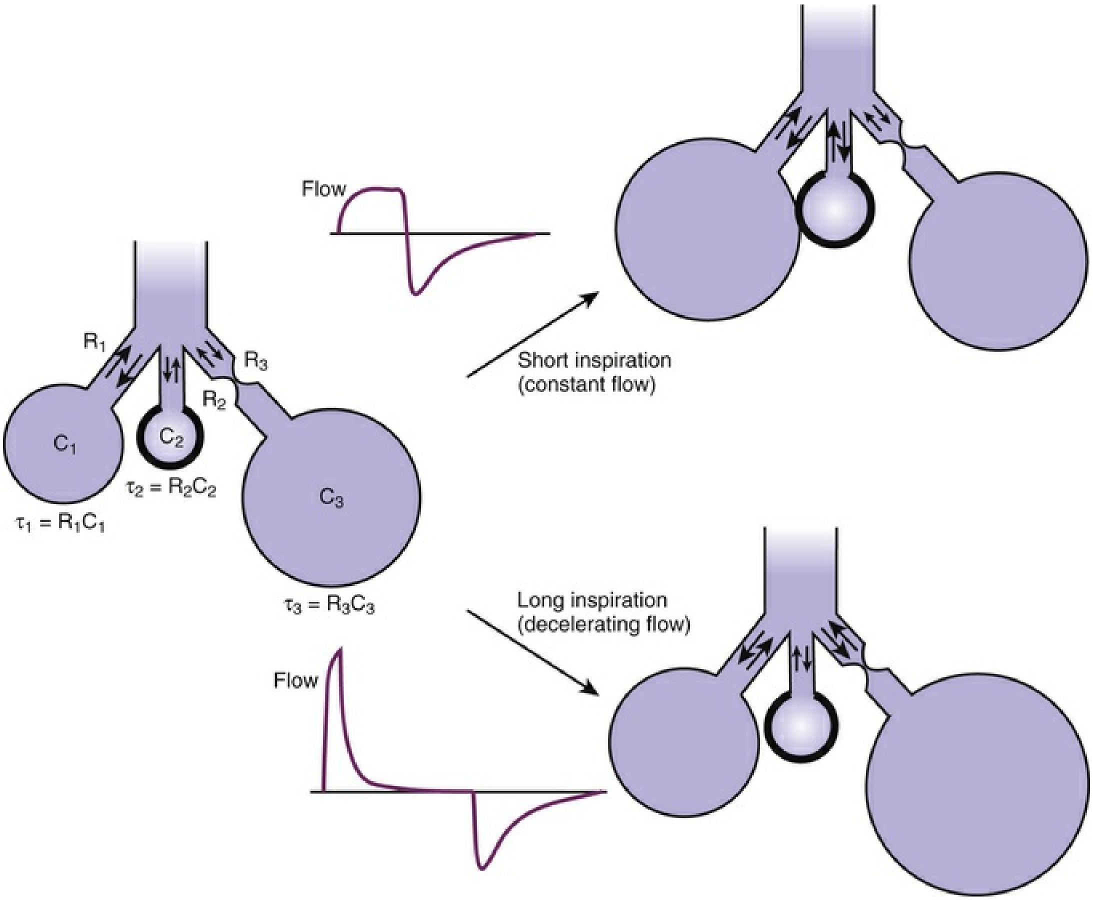

FIG. 49.9 Schematic representation of the lung showing the effects of ventilatory pattern on the distribution of inspiratory gas flow. The rate of inflation or deflation of an airway-alveolar unit can be characterized by a time constant *(τ)* equal to the product of its resistance *(R)* and compliance *(C).* Three types of units are represented in the scheme (each identified by the corresponding numerical subscript): (1) a normal unit with normal compliance and resistance (normal *τ*); (2) a restrictive unit with decreased compliance and normal resistance (short *τ*); and (3) an obstructed unit with normal compliance and increased resistance (long *τ*). Inflation with a decelerating pattern of flow (typical of modern pressure-controlled ventilator modes) favors units with normal compliance (1 and 3). Inflation with a short inspiratory time and a constant flow (more typical of volume-controlled modes) directs flow away from the unit with a long time constant (3), causing the tidal volume of the other units (1 and 2) to be disproportionately larger relative to their compliance.

Restrictive and Obstructive Respiratory Disease

As seen, inertial pressure losses are relatively insignificant at normal breathing frequencies in children, and viscoelastic pressure losses are usually small and lumped together with other dissipative pressure losses. Therefore the pressure that the respiratory muscles must generate to produce a certain volume excursion of the thorax can simply be considered the sum of elastic and resistive pressures that need to be overcome in the process (see Eqs. 6 and 7). Because work is calculated by

integrating these pressures relative to the same volume change, it immediately follows that the total work done by the respiratory muscles is the sum of the works done to overcome elastic and resistive pressures.

When applying these formulations, it is important to realize that elastic and resistive forces do not always act in the same direction. During inspiration, the respiratory muscles must generate the force to overcome both elasticity and flow resistance. Thus both elastic and resistive works have the same sign and their effect on total work is additive. During expiration, however, the elastic recoil of the lungs normally provides the force needed to overcome resistance. Elastic and resistive works are of similar magnitude and opposite sign, and the total work done by the muscles is zero. When there is intrathoracic airway obstruction, however, the absolute value of resistive work often exceeds that of elastic work. Under these circumstances the expiratory value of total work is no longer negligible and the expiratory muscles must do the balance of the expiratory work.

The term *restrictive respiratory disease* encompasses all conditions in which elastic or nondissipative work is primarily increased. One could also say that restrictive disease is caused by a decrease in thoracic compliance. Whether originating in the lungs or the chest wall, a decrease in thoracic compliance has two important mechanical consequences. First, the work of breathing increases, but only during inspiration; expiration continues to be passive and, in fact, takes place at a faster rate as elastic recoil increases. Second, the relaxation volume of the thorax and FRC decreases. The resultant decrease in lung volume, which may further reduce lung compliance, may be more pronounced in the infant, whose resting relaxation volume is already low. At low lung volumes, alveoli lack the support provided by the recoil of neighboring structures at higher volumes (mechanical interdependence[15]) and become inherently unstable, particularly if the surfactant system is affected by the disease and surface tension is increased. To prevent alveolar collapse, infants and small children with restrictive respiratory disease often close their glottis toward the end of expiration, causing each breath to end in a grunt. PEEP and continuous positive airway pressure are effective therapeutic modalities to achieve the same objective of preserving the end-expiratory inflation volume.[31,32] Deep lung inflations during positive pressure ventilation (often described as recruitment maneuvers) also may maintain unstable alveoli open for a period. This effect of volume history on alveolar volume decreases the work needed for spontaneous breaths following the inflation, adding to the more obvious benefits of intermittent mandatory ventilation in patients with restrictive lung disease.

Obstructive respiratory disease includes all conditions in which resistive or dissipative work is predominantly increased. The small caliber and high wall compliance of the developing airways render the infant and child more vulnerable to the development of airway obstruction.[33] Under normal breathing conditions, the small caliber of the airways represents no mechanical disadvantage because there is good correspondence between airway cross-sectional area and gas flow. When obstruction develops, however, airway resistance increases as an exponential function of the reduction in airway diameter (see Eq. 11). Because the same absolute decrease in caliber causes a much greater proportional reduction in airway diameter in a small than in a large airway, obstructive lesions tend to have more severe consequences in children than in adults.

Determinants of Respiratory Efficiency

The respiratory system has a notable ability to compensate for mechanical dysfunction. However, compensation does not come cheap. It raises the work of breathing in almost every instance, usually by combining increases in the force of contraction of the respiratory muscles with changes in ventilatory pattern. If the increase in work is sufficient to overcome the additional restrictive and obstructive loads applied on the respiratory system, minute alveolar ventilation and arterial P_{CO_2} are maintained within normal limits and respiratory failure is averted. In contrast, if the metabolic and contractile machinery of the respiratory muscles cannot meet the greater work demands, alveolar ventilation becomes insufficient to support gas exchange and respiratory failure ensues.

In the final analysis, the success or failure of the compensatory effort is a simple matter of balance between the energy resources available to the respiratory muscles and the energy demands imposed on these muscles. The energy resources are relatively well defined and limited by the blood supply of the muscles, their ability to metabolize substrates, and the internal efficiency of the muscle's metabolic apparatus. The energy demands on the respiratory muscles are more variable, however, and depend on the workload these muscles must perform per unit of time (ie, the power they must generate) and the overall efficiency with which the work is performed.

In thermodynamic terms, efficiency is defined as the proportion of the free energy available within a system that is transformed into external work (Eq. 1). In the case of the respiratory system, this notion can be reshaped to define efficiency as the quotient of respiratory muscle breathing power (W × t) divided by respiratory muscle energy consumption.

The breathing power is difficult to measure in spontaneously breathing subjects (remember that the respiratory muscles are themselves part of the chest wall) and has to be estimated from the volume-pressure relationships of the lungs. The energy consumption of the respiratory muscles is in turn estimated from their oxygen consumption,[34] which we can compute (also suboptimally) as the difference between the total body oxygen consumptions measured during spontaneous and supported ventilation. Some obvious sources of energy consumption, which are not included in the breathing power, reduce the respiratory system's efficiency. For example, the work of breathing does not account for isometric activity of the respiratory and postural muscles, which is not proper work in a physical sense (no volume change) but consumes energy. Other forms of volume-pressure work usually are not taken into account when calculating respiratory efficiency, so they also become sources of apparent inefficiency. The work performed to inflate the chest wall, as we just noticed again, cannot be determined during spontaneous breathing when contraction of the muscles changes the wall's passive properties. Similarly, the work done to deform the rib cage is difficult to measure and often is ignored. Thus it is not surprising that the published efficiencies tend to be artifactually low.[35,36]

As defined here, the poor overall efficiency of the respiratory system implies that, during each breathing cycle, a substantial amount of energy derived from metabolic substrates is dissipated as heat and cannot be converted into volume-pressure work. Respiratory disease can increase this energy dissipation by various mechanisms, leading to efficiency values as low as 1% to 3%.[35,37,38] Disease-induced alterations in

chest wall configuration, for example, can limit force generation by the muscles, thus interfering with the transformation of chemical energy into mechanical energy.[39] Changes in the geometry of the chest wall also modify the spatial relationships of the muscles and can interfere with the transformation of mechanical energy into work. Finally, disease-related anomalies in the contractile state of the muscles produced by fatigue or poor nutrition further decrease muscle force and the work of breathing without decreasing muscle energy demands.[40,41]

Power of Breathing and Breathing Frequency

Unlike work, which is a function of the volume-pressure characteristics of the thorax, respiratory power (work/time) is influenced by the pattern of breathing. It has been held for some time that, at any given time, each subject has an optimal breathing frequency at which minimum power, and thus a minimum energy consumption, is necessary to attain a certain minute alveolar ventilation (Fig. 49.10).[36,42] Although this view has been challenged by those who believe that breathing frequency is adjusted to minimize average muscle force rather than power (after all, there are no known energy or power receptors anywhere in the body),[43] it is a common clinical observation that different types of mechanical derangement result in distinctive patterns of breathing. These patterns generally agree with the principle of minimal power expenditure. For instance, patients with restrictive lung disease breathe rapidly and shallowly. In contrast, patients with airway obstruction breathe more slowly and prolong their inspiration or expiration, depending on whether the obstruction is extrathoracic or intrathoracic. By simply inspecting the effort and frequency of the breathing movements, the clinician can therefore assess not only the severity but also the specific nature of a patient's respiratory dysfunction.

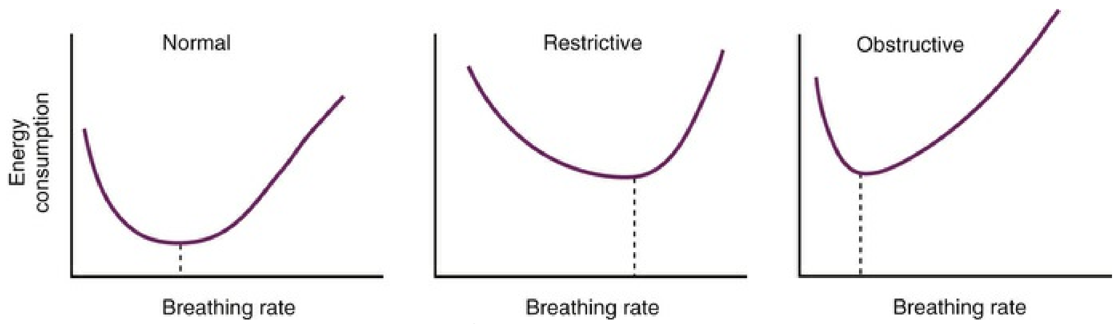

FIG. 49.10 Each combination of mechanical conditions is associated with an optimal breathing rate for which the power (work × time) and thus the energy consumption of breathing are minimal. Restrictive disease increases the optimal rate, while obstructive disease decreases it. Actual breathing rates adhere remarkably to predictions on the basis of minimal power. Consequently, it is safe to assume that, under most circumstances, the presence of tachypnea is indicative of a restrictive derangement and that a decrease in respiratory rate or, more precisely, a prolongation of inspiration or expiration indicates an obstructive derangement.

Alterations in Chest Wall Configuration

Diaphragmatic Configuration

The amount of force developed by a muscle depends on its resting length. An optimal resting length for which maximal force is developed can be defined for each muscle. In the case of the diaphragm, the optimal length is attained at thoracic volumes close to the normal FRC. At these volumes, the muscle has the shape of a dome-capped cylinder, a configuration that has several advantages. First, diaphragmatic contraction shortens the cylinder in the axial direction, producing a pistonlike motion that displaces more volume than if the diaphragmatic dome simply became flatter (assuming the same degree of fiber shortening). Second, the descent of the diaphragmatic dome increases the surface of contact between the rib cage and the lungs. Therefore the increase in lung surface produced by lung inflation can be accommodated without changing the shape of the lung or the chest wall. Finally, at normal breathing volumes, the sides of the diaphragmatic cylinder are apposed to the internal surface of the rib cage. This area of apposition establishes a mechanical link between intraabdominal pressure and lung volume.[44] As the diaphragm contracts during inspiration, intraabdominal pressure increases, pushing the lower portion of the rib cage forward and laterally. Thus diaphragmatic contraction has an additional contribution to lung inflation at low energy cost and may help to stabilize the lower rib cage against inspiratory distortion.

The configuration of the chest in the infant and small child minimizes these advantages. At these ages, the lower portion of the infant's rib cage has relatively large anteroposterior and lateral diameters. As a result, the insertions of the diaphragm are spread out, thereby reducing the axial shortening range of the muscle. Moreover, the lack of a substantial area of apposition of the diaphragm and rib cage abolishes the inspiratory and stabilizing effects of intraabdominal pressure on the rib cage.

Thoracic hyperexpansion and abdominal distension exaggerate these limitations by widening the diameters of the lower portion, spreading out the diaphragmatic insertions. The length of the muscle fibers is diminished to a suboptimal length, and the force generated during inspiration is decreased. Abdominal distension has the additional disadvantage of raising intraabdominal pressure, which opposes diaphragmatic contraction and raises the work that the muscle has to do.

Rib Cage Distortion

Until now, we have assumed that the rib cage and abdomen have the same configuration during spontaneous breathing and passive inflation-deflation maneuvers. This assumption implies that all the various parts of the chest wall move with a single degree of freedom and that there are no volume shifts between parts. However, it has been known for quite some time that, under certain conditions, the rib cage and abdomen can change volume independently of one another and even in opposite directions.[45] In other words, the chest wall has multiple degrees of freedom and can undergo regional distortion.

Regional chest wall distortion results from the coupling of changes in pressure (pleural or intraabdominal) and the local compliances of the rib cage and abdominal wall. Rib cage distortion is more pronounced during inspiration, when pleural pressure decreases with respect to atmospheric pressure or the diaphragm pulls the

rib cage by its costal insertions, forcing the thoracic wall inward in the expiratory direction. This inward movement of the rib cage causes visible retractions in areas where the chest wall has no bony support (intercostal, subcostal, or suprasternal spaces) or where the support has been abnormally weakened (eg, costal fractures). Abdominal distortion, in contrast, usually involves alterations in the contractile state of the diaphragm or abdominal wall muscles. When one hemidiaphragm becomes paralyzed, for example, the negative pleural pressure generated by other inspiratory muscles pulls the paralyzed muscle upward, into the rib cage, during inspiration. As a result, the abdominal wall of the affected side moves paradoxically in the inward direction, and the chest wall becomes distorted. As another example, contraction of the abdominal muscles stiffens the abdominal wall, raising intraabdominal pressure and shifting all volume changes to the rib cage during both inspiration and expiration.

The developing chest wall is particularly susceptible to distortion. As we have seen, the rib cage is compliant in the newborn.[2,4,46] Although this high compliance facilitates passage through the birth canal, it also promotes distortion of the rib cage during inspiration. In addition, the intercostal muscles, whose main contribution to breathing is to stabilize the rib cage by contracting simultaneously with the diaphragm, appear to have decreased tone at early ages, especially during rapid eye movement sleep and in preterm infants.[47] Finally, the lack of a substantial area of apposition between the diaphragm and the rib cage removes the stabilizing effect of the intraabdominal pressure on the lower rib cage. Accordingly, in infants chest wall retractions tend to develop in the presence of minimal mechanical lung dysfunction.

Chest wall distortion represents a pressure-induced change in volume, and therefore it constitutes a form of work. Distortional work is usually not computed as part of the work of breathing. However, it has a measurable energy cost, and therefore it needs to be viewed as a source of respiratory inefficiency. Both the distortional work and its energy cost can be better understood if we analyze the volume-pressure relationships of the thorax in the particular case of rib cage retractions during inspiration. Regardless of whether such retractions are present, at any point, the volume change of the lungs (ΔV_L) must be equivalent to the sum of the volume changes of the rib cage (ΔV_{rc}) and abdomen (ΔV_{ab}):

$$\Delta V_L = \Delta V_{rc} + \Delta V_{ab} \quad \textbf{Eq. 49.12}$$

Consequently, if ΔV_L is to remain constant, decreases in ΔV_{rc} caused by rib cage retractions during inspiration must be accompanied by a proportional increase in ΔV_{ab} (Fig. 49.11). If, as often occurs, ΔV_{rc} is negative, then ΔV_{ab} becomes greater than ΔV_L. Because the volume displacement of the diaphragm approximates ΔV_{ab}, chest wall retractions inevitably result in an increase in the diaphragmatic excursion.

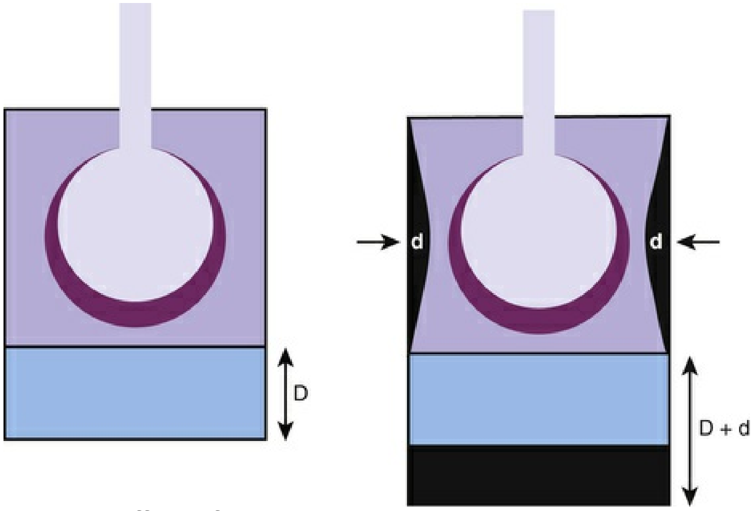

FIG. 49.11 Effect of inspiratory rib cage distortion on the volume displacement of the diaphragm. When the rib cage caves inward during inspiration, to generate the same tidal volume in the lungs (shown in *red*), the diaphragm must increase its volume excursion above the nondistorted value *(D)* by an amount equivalent to the volume of the inward movement of the rib cage *(d).* Rib cage distortion usually relates to the combination of an increased rib cage compliance and increased respiratory effort, which translates into more negative pleural pressures acting on the inner surface of the rib cage. However, it can occur without apparent increase in effort, especially in premature infants, or as a result of disease- or trauma-induced chest wall distortion (eg, rib fractures or unilateral phrenic palsy).

The amount of work done by the diaphragm is calculated by integrating the pressure developed by the muscle relative to the volume displacement produced by the diaphragmatic contraction. In practical terms, the pressure developed by the diaphragm or transdiaphragmatic pressure is defined as the difference between the intraabdominal pressure (P_{ab}, often estimated from measurements of gastric pressure) and the pleural pressure (P_{pl}, estimated from the esophageal pressure). The volume displaced by the diaphragm is estimated as ΔV_{ab} in Eq. 12. Thus diaphragmatic work (W_{di}) can be computed as:

$$W_{di} = \int (P_{ab} - P_{pl}) \cdot dV_{ab} \qquad \textbf{Eq. 49.13}$$

The work done on the airways and lungs to move gas in and out of the alveoli (see Eqs. 3 and 4) is:

$$W_L = \int (P_M - P_{pl}) \cdot dV_L \qquad \textbf{Eq. 49.14}$$

P_{ab} is generally greater than P_M (which is 0 in the absence of positive airway pressure), particularly in a recumbent subject. In the presence of rib cage retractions, dV_{ab} greatly exceeds dV_L and consequently W_{di} substantially exceeds W_L. The

volume displacement of the diaphragm may be up to twice the tidal volume of the lungs in premature infants without apparent lung disease,[48] an increase that could be responsible for the poor weight gain and development of fatigue of infants recovering from the respiratory distress syndrome.

Alterations in Contractile State of the Respiratory Muscles

Respiratory efficiency is affected by the functional state of the respiratory muscles. Sustained increases in activity will likely eventually result in decreased contractile force and lower minute alveolar ventilation, a condition often classified as muscle fatigue. When muscle fatigue is present, the energy consumption of the muscle may be increased with respect to the actual work performed. Similar decreases in contractility without a decrease in energy consumption can be present in a variety of clinical situations. Some result from an imbalance between the energy demands of the muscle's contractile machinery and its substrate availability (eg, shock[49]). Others are simply the expression of the inadequate coupling of the excitation-contraction processes inside the muscle cell, changes in the recruitment of specific fiber populations within the muscle,[50] or chronic depletion of the muscle's energetic resources as a result of malnutrition.[40]

Conclusion

Although the developing respiratory system has obvious mechanical disadvantages, the reader should not be left with the idea that infants and children are constantly on the brink of respiratory failure. Quite the contrary, they have a remarkable capability to tolerate respiratory disease. This capability is in great part based on a proficient system of mechanical compensation. The information contained in this chapter is intended to provide an overview of the factors involved in both mechanical dysfunction and its compensation. Unfortunately, the physiologic principles underlying the basic concepts presented here are receiving less and less attention in our training programs. The reader is encouraged to visit and study the many classical references contained in the bibliography. Although many of them certainly show the signs of age, they provide the critical foundation for a more rational approach to the therapy of respiratory disease in the critically ill child.

CHAPTER 50

Specific Diseases of the Respiratory System

Upper Airway

David Jardine, Andrew Inglis Jr., Agnes I. Hunyady

PEARLS

- Diseases leading to compromise of the airway are the most frequent causes of cardiac arrest in pediatric patients. A small reduction in the caliber of the child's airway may lead to a life-threatening reduction of airflow.
- Laryngomalacia is the most common congenital anomaly of the larynx. Infants tend to outgrow this problem during the first year of life; however, the condition may be of sufficient severity in some infants that activities such as feeding are compromised.
- The trachea may be compressed by the presence of an abnormal vascular structure. Children affected by this problem may have such diverse symptoms as stridor, wheezing, lobar atelectasis, or recurrent pulmonary infections.
- The practice of treating laryngotracheobronchitis with corticosteroids is a standard of care, especially for hospitalized patients. A meta-analysis in which the efficacy of corticosteroids was evaluated suggests that corticosteroids may reduce the need for endotracheal intubation and hasten improvement when given in the first 24 hours of illness.
- Epiglottitis, a bacterial infection of the supraglottic tissues historically caused by *Haemophilus influenzae* type B, is now most frequently caused by group A β-hemolytic streptococcus.
- Patients with bacterial tracheitis usually do not respond to inhaled racemic epinephrine, have a high fever, and appear very ill.

Diseases leading to compromise of the airway are the most frequent causes of cardiac arrest in pediatric patients. Various processes can lead to respiratory failure, including disorders of the respiratory tract causing obstruction, mechanical

impairment of ventilation (pneumothorax, chest wall injury), neuromuscular failure (severe weakness, coma), and failure to deliver oxygen to the tissue (cardiac insufficiency, septic shock).[1] Prompt recognition of the general process causing respiratory failure quickly eliminates many diagnostic possibilities, permitting the clinician to focus on a smaller group of causes and a narrower range of therapeutic interventions. Specific diseases of the airway leading to obstruction are discussed here.

The small size of the infant's trachea makes airway obstruction more likely and particularly dangerous. The normal anteroposterior diameter of the infant's glottis is 4.5 mm. One millimeter of circumferential tracheal edema reduces the glottic lumen to 30% of its normal size. Poiseuille's law stipulates that laminar flow of gas through a tube is inversely proportional to the fourth power of the radius of the lumen:

$$R = \frac{8\,ln}{\pi r^4}$$

where *R* is the resistance to gas flow, *l* is the length of the tube, *n* is the viscosity of the gas, and *r* is the radius. Unfortunately, airflow through a narrowed trachea is usually turbulent, which worsens the situation because resistance to turbulent flow of gas past an obstruction is inversely proportional to the fifth power of the radius of the lumen.[2,3] Gas exchange will be dramatically reduced by minor degrees of impingement on an infant's trachea. A child may not tolerate lesions that would not even produce symptoms in an adult. Rapid triage and expeditious treatment of upper airway obstruction in children are essential.

Initial Management

Once the diagnosis of upper airway obstruction is made, efforts should be undertaken to minimize disturbing the patient unless the respiratory embarrassment is severe enough to be life threatening. Airway obstruction often worsens when infants and children are alarmed during a diagnostic evaluation. Humidified oxygen should be administered through a nasal cannula or facemask. These devices may frighten younger children who may more readily accept oxygen delivered through flexible tubing held by the parent. If the child will tolerate placement of a pulse oximeter probe, this provides a noninvasive way of evaluating oxygenation. Because arterial oxygen saturation is easily determined noninvasively, arterial blood gas is should be reserved to determine which patients may be hypercapnic; however, this procedure will further upset the child. Using clinical judgment to assess the severity of airway obstruction is a standard practice.[4]

After upper airway obstruction has been diagnosed, a combination of physical and radiographic findings may help localize the lesion. Once the anatomic site of the lesion has been identified, the diagnostic possibilities narrow greatly. During the diagnostic evaluation, the child may sit in the parent's lap if this reduces anxiety. This position usually does not interfere with diagnostic evaluation, like lateral neck and chest radiography.

Gentle, nonthreatening examination of the patient's head and neck may reveal the cause of the illness. During the initial evaluation, an assessment should be made

regarding the likely location of the obstruction. Extrathoracic airway obstruction usually results in stridor (the obstruction is most severe during inspiratory phase), whereas intrathoracic airway obstruction usually results in wheezing (the obstruction is most severe during expiratory phase). Localizing the obstruction in this manner helps to narrow the diagnostic possibilities. In the emergency room setting, it may be possible to use a small fiberoptic scope to identify supraglottic causes of airway obstruction. This should not be attempted unless individuals are present who are skilled in the fiberoptic evaluation of the pediatric airway and if such an examination does not worsen the patient's distress.

The initial evaluation should be accomplished expeditiously with the goals of making decisions about the management and further evaluation of the patient with upper airway compromise. In the case of severe respiratory compromise, it may be necessary to plan for invasive procedures (endotracheal intubation or operative intervention) while the diagnostic evaluation is being performed. Finally, it should not be forgotten that pulmonary edema might follow relief of severe upper airway obstruction.[5] Postobstructive pulmonary edema may be severe enough to require intensive therapy, including endotracheal intubation, mechanical ventilation, and positive end-expiratory pressure.

Congenital Malformations

A variety of congenital malformations can affect the pediatric airway. Many of these become evident in the delivery room. Some congenital malformations do not present until the child is older and somatic growth has made the airway impairment more evident.

Choanal Atresia

Choanal atresia is estimated to occur about once in every 5000 to 9000 live births.[6] Choanal atresia is seen commonly with other defects, especially CHARGE syndrome, which accounts for 25% of all patients with choanal stenosis.[7] Unilateral choanal atresia, the most common form, is often seen without accompanying congenital defects and may not be diagnosed at the time of delivery. Bilateral choanal atresia almost always occurs in the presence of other congenital defects.[7] For the first 5 months of life, many infants breathe only through their noses and do not open their mouths when the nasal passages are occluded; consequently, bilateral choanal atresia often results in respiratory distress shortly after birth. Bilateral choanal atresia (Fig. 50.1) is diagnosed through examination of the naris with the mouth closed. If no airflow is present, a presumptive diagnosis of choanal atresia is established. Some authorities advocate passing a thin, flexible catheter through the naris. This will confirm the diagnosis of choanal atresia; however, if the symptoms are resulting from choanal stenosis, edema formation following even minor trauma of the nasal mucosa after catheter placement may lead to complete occlusion of the nasal airway and worsening of respiratory distress. Surgery is indicated for the correction of bilateral choanal atresia if the infant has symptoms[8] (Fig. 50.2). Infants with bilateral choanal atresia generally have surgery within the first 3 months of life, whereas infants with unilateral choanal atresia typically have surgery after the second year of life.[9] Various surgical approaches and adjuncts have been reported;

however, there is insufficient evidence to indicate which are the most successful.[10] Although choanal atresia is the most common cause of nasal airway obstruction, midline nasal masses such as meningoencephaloceles, gliomas, or dermoid tumors can also cause obstruction. Because these lesions may originate from within the cranial vault, computed tomography (CT) scanning or magnetic resonance imaging (MRI) should be performed before a biopsy or surgical correction of the abnormality is attempted.[11]

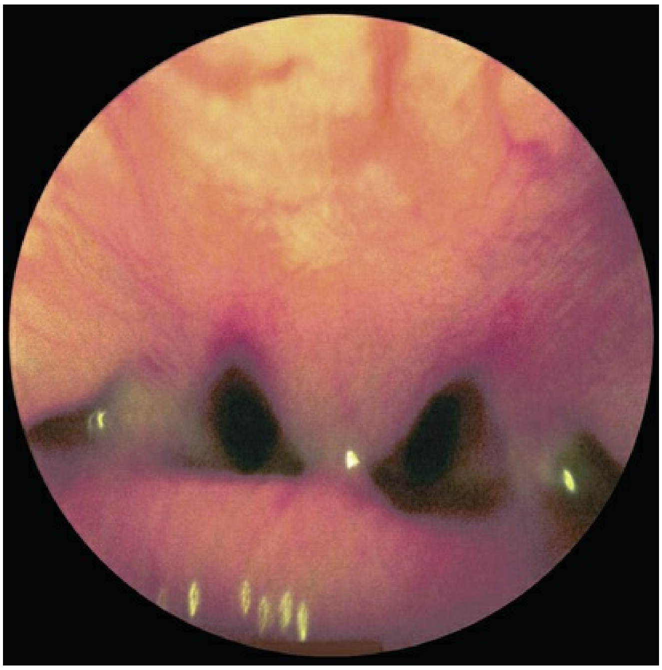

FIG. 50.2 Choanal atresia after repair. View from the posterior of the nasopharynx demonstrating patency of choanae following surgery. (Copyright Andrew F. Inglis, Jr.)

Laryngomalacia

Laryngomalacia is the most common congenital anomaly of the larynx. The infant has inspiratory stridor that is exacerbated by crying or distress. Although no gross anatomic abnormalities are present, the laryngeal cartilages lack their usual rigidity. When the larynx is observed during fiberoptic examination of the glottis, the arytenoid cartilages and supraglottic structures collapse inward (toward the glottis) during inspiration, leading to inspiratory stridor. During exhalation, the laryngeal structures are more patent but may still be narrowed compared to a normal infant larynx (Fig. 50.3). The negative intrathoracic pressure generated during inspiration contributes to a high incidence of gastroesophageal reflux[12] and pulmonary aspiration.[13,14]

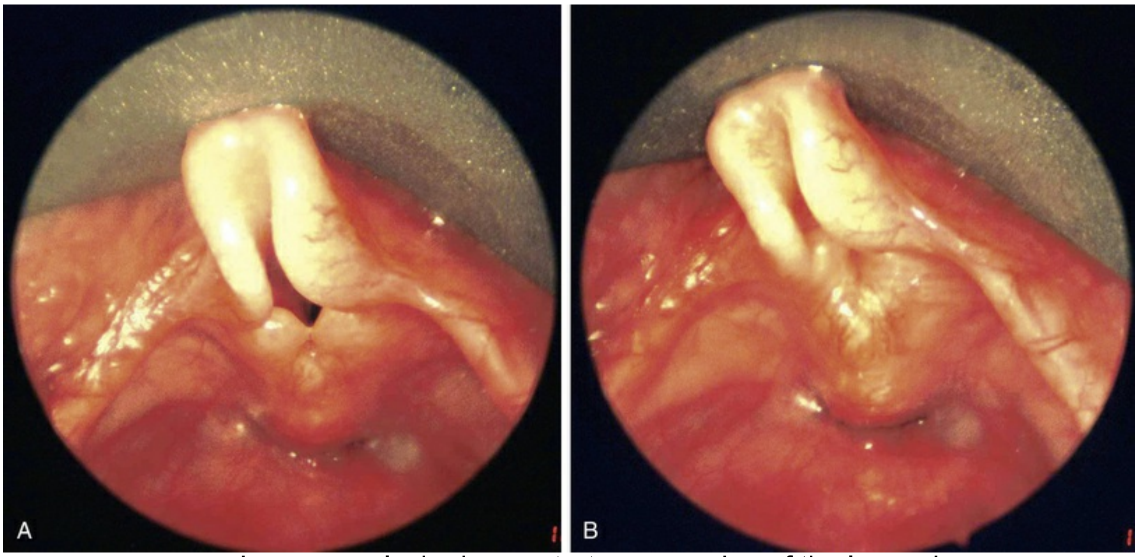

FIG. 50.3 Laryngomalacia demonstrates narrowing of the larynx in inspiration and expiration. During exhalation (A) note the tightly curled epiglottis and the slitlike opening to the laryngeal inlet caused by the medialization of the superior edges of the aryepiglottic folds. During inhalation (B) the aryepiglottic folds are drawn further inward, causing obstruction of the larynx. (Copyright Andrew F. Inglis, Jr.)

In some patients with laryngomalacia, gastroesophageal reflux may be the primary cause of the airway compromise, whereas in others it may be a significant cofactor exacerbating preexisting neurologic or anatomic abnormality.[15] The respiratory embarrassment associated with this problem is usually minor and self-limited, although hypoxia and hypercapnia have been documented.[16] During infancy, laryngomalacia accompanies sleep apnea in 27% of patients.[17] Infants tend to outgrow this problem during the first year of life; however, the condition may be severe enough in some infants to compromise activities such as feeding. In the most severe cases, surgical intervention may be necessary.[18] The goal is to relieve airway obstruction by excision of tissue that collapses into the glottis during inspiration.

Laryngeal Webs, Stenosis, and Tumors

Laryngeal webs usually occur at the level of the glottis and are usually located anteriorly. These may be congenital or acquired and are generally thin membranes of soft tissue that partially occlude the tracheal opening, producing symptoms of feeble cry and dyspnea shortly after birth (Fig. 50.4).[19] Surgical lysis of these lesions corrects the problem. Laryngeal cysts and laryngoceles are soft tissue masses that protrude into the glottic lumen (Fig. 50.5). The resulting respiratory compromise is usually recognized as inspiratory stridor. Treatment is surgical excision of the lesion.[20]

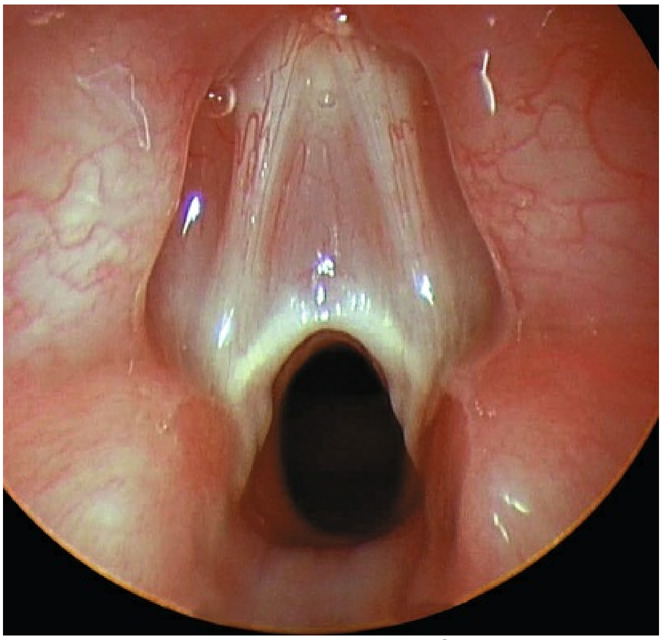

FIG. 50.4 A laryngeal web occludes most of the tracheal lumen in this patient. This web, which is a thin membrane of soft tissue at the level of the glottis, has many of the features typical of this class of lesions. (Copyright Andrew F. Inglis, Jr.)

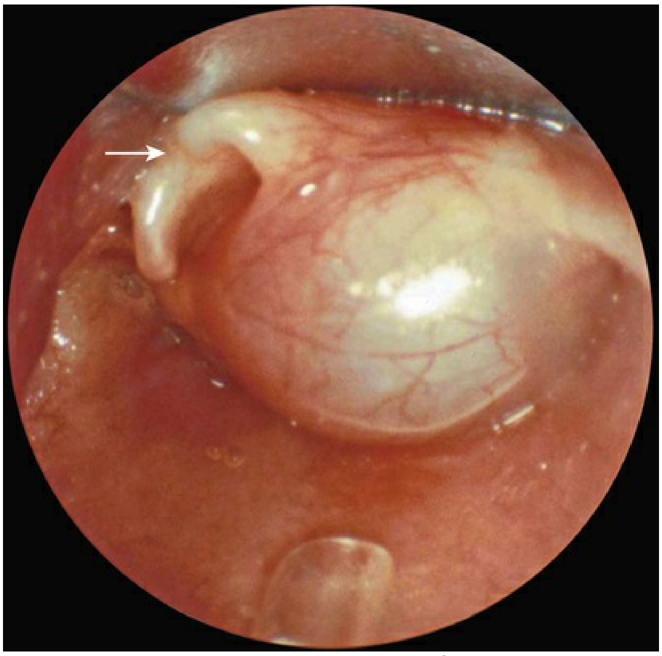

FIG. 50.5 A large laryngeal cyst protrudes from the lateral wall of the trachea, just below the level of the glottis. (Copyright Andrew F. Inglis, Jr.)

Another lesion presenting as inspiratory stridor is congenital laryngotracheal (subglottic) stenosis. This is the second most frequent cause of stridor in infants.[21] The infant with this problem may have symptoms when newborn but often comes to medical attention later when the tracheal edema produced by a minor respiratory infection causes severe inspiratory stridor. This may be initially diagnosed as croup

(laryngotracheobronchitis) but is noted to recur with each subsequent upper respiratory infection. Although the diagnosis of laryngotracheal stenosis may be made radiographically, it is usually established with bronchoscopy. If endotracheal intubation is necessary, a smaller than normal endotracheal tube should be used to reduce trauma and ischemia of the subglottic tissues. Depending on the severity of the lesion, surgical intervention may be necessary (see "Laryngotracheal (Subglottic) Stenosis" for details of the surgical procedures).

Soft tissue masses may reduce the caliber of the tracheal lumen, either by extrinsic compression, as happens with a cystic hygroma, or by growth into the tracheal lumen from the tracheal wall, as happens with a hemangioma. Although these lesions may be present at birth, they often do not produce symptoms for the first few months until the growing lesion further impinges on the trachea. Although surgery is frequently used for treatment of tracheal hemangiomas,[22] pioneering work by Judah Folkman was instrumental in demonstrating that some of these lesions respond to steroid therapy.[23]

Vascular Impingement on the Trachea

The trachea may be compressed by the presence of an abnormal vascular structure (Fig. 50.6).[24] The innominate artery is the most common vessel causing tracheal compression. Vascular rings and enlarged pulmonary arteries are also known to cause tracheal compression, as are a variety of other vascular abnormalities.[25] These lesions may present with physical findings such as stridor or wheezing. Alternatively, the patient may be symptom-free but may suffer respiratory problems such as recurrent lobar atelectasis or frequent pulmonary infections. For this reason, it is difficult to recognize a vascular ring as the underlying cause of illness.[26] Careful inspection of the chest radiograph may reveal indentation of the trachea, but often this sign is absent. Barium swallow has been the historic method of diagnosing vascular impingement of the trachea. CT scanning and MRI have become the diagnostic modalities of choice (Figs. 50.7 and 50.8). These noninvasive methods are effective at showing complex three-dimensional cardiovascular anatomy, especially the extracardiac morphology. Treatment involves surgical correction of the vascular anomaly, in severe cases.[27] Respiratory distress may persist postoperatively because prolonged compression of the trachea has made the affected segment softer and collapsible.

Bronchomalacia and Intrathoracic Tracheomalacia

During normal respiration, the upper airway is subject to cycles of positive and negative intraluminal pressure. The cartilaginous components of the upper airway are rigid ringlike structural elements that resist the tendency to collapse caused by the cycling of pressure within the airway lumen. When these structures lack their characteristic rigidity, the mechanics of breathing are altered.[28] The symptoms produced by these changes depend on the location of the damaged cartilages. Characteristically, intrathoracic cartilaginous lesions such as bronchomalacia or tracheomalacia impede exhalation. The diagnosis of airway malacia should be suspected in children who have recurrent lower airway infections or asthmatic symptoms that do not respond to medical therapy.[29] Confirmation of this problem may be made through observation of collapse of the upper airways during active exhalation, such as occurs while crying. Collapse can be observed with several diagnostic modalities including fluoroscopy, flexible or rigid bronchoscopy, and ultrafast CT scanning.[30]

Although these lesions may be congenital, many of the cases of tracheomalacia and bronchomalacia seen in the pediatric intensive care unit (PICU) are the result of an infectious or mechanical insult to the trachea. Infants with bronchopulmonary dysplasia and persistent respiratory problems may be affected by bronchomalacia alone or in combination with tracheomalacia.[31] Airway malacia is frequently associated with purulent bacterial airway infections that may require recurrent antibiotic therapy.[32] The obstructive symptoms produced by these lesions may be

relieved by continuous positive airway pressure to maintain patency of the airway during exhalation.[33] The level of continuous positive airway pressure necessary to improve respiratory function may be assessed clinically (relief of obstructive symptoms), mechanically (measurement of flow-volume loops), or bronchoscopically (maintenance of airway patency throughout the respiratory cycle).[34] With sufficient time, many of these infants outgrow their respiratory difficulties. As an alternative to tracheostomy and positive airway pressure, some have advocated surgical intervention with pericardial flap aortopexy[35] or, in extreme situations, metallic airway stents.[36]

Infectious Processes

A variety of infectious processes may affect the pediatric airway. Poiseuille's law dictates that airway compromise from the swelling that accompanies an infectious process is greater in infants and young children than it is in adults. A small reduction in the caliber of the smaller child's airway may lead to a life-threatening reduction of airflow.

Laryngotracheobronchitis

Laryngotracheobronchitis (croup) is a common childhood infection, affecting approximately 3% of children each year.[37] Parainfluenza virus is the most common cause (approximately 75% of cases),[37] whereas coronavirus and rhinovirus constitute the remainder of infections.[38] This is a seasonal illness, occurring predominately during winter months and most commonly affecting children from age 6 months to 3 years. There is frequently a history of prodromal infection accompanied by an unusual cough (described as sounding like the bark of a seal). Swelling of the tracheal mucosa in the subglottic region causes airway compromise (Fig. 50.9). Medical attention is usually sought when the child develops inspiratory stridor and respiratory distress. Various scales have been devised to quantify the severity of the stridor to document the progression of the illness and the response to therapy. One of the most commonly employed scales is the Westley scale,[39] which has been validated (Table 50.1).[40]

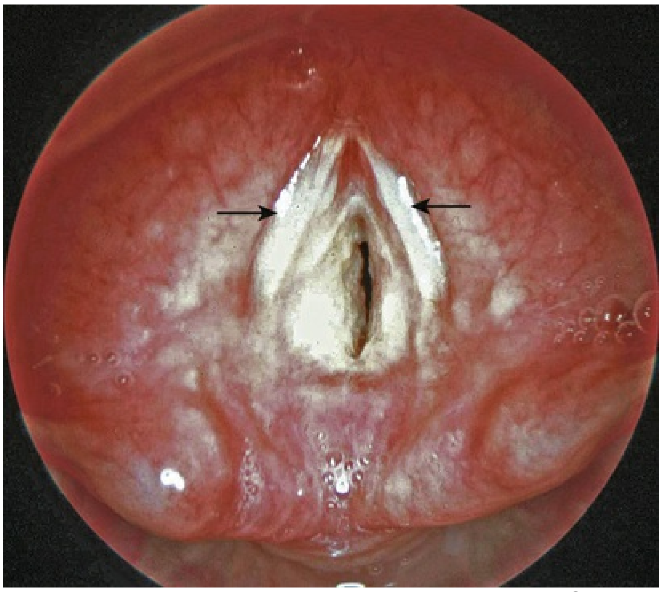

FIG. 50.9 Laryngotracheobronchitis: Below the level of the vocal cords the trachea appears swollen and the tracheal walls are covered with purulent material (vocal cords are indicated by *arrows*).

TABLE 50.1
Westley Croup Score

	0	1	2	3	4	5
Chest wall retraction	None	Mild	Moderate	Severe		
Stridor	None	With agitation	At rest			
Cyanosis	None				With agitation	At rest
Level of consciousness	Normal					Disoriented
Air entry	Normal	Decreased	Markedly decreased			

Total score ranges from 0-17 points (severe croup).[37]

From Johnson DW. Croup. BMJ Clin Evid. 2014;2014.

When a chest radiograph is obtained during an episode of laryngotracheobronchitis, the trachea is seen to have a gradual progressive narrowing of its lumen, reaching the narrowest point just below the vocal cords (the "steeple sign") (Fig. 50.10). The upper glottis, as seen on a lateral neck radiograph, is normal.

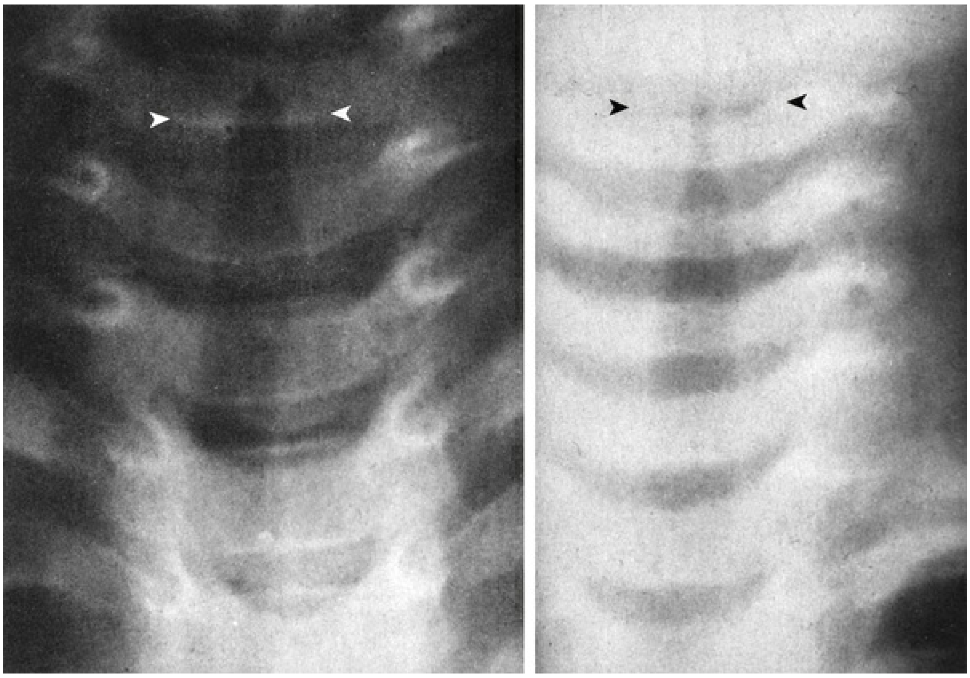

FIG. 50.10 Anteroposterior radiograph of the neck. *(Left)* A normal tracheal air column (between the *arrows*). *(Right)* Trachea narrowed by laryngotracheobronchitis.

Many care providers believe that exposing the child to cold or misty air often dramatically improves the symptoms, although evidence in support of this therapy is lacking.[37,41,42] When the illness is refractory to these measures, racemic epinephrine has been shown to produce measurable reduction of airway obstruction.[43] This probably is accomplished by stimulation of the α-adrenergic receptors, producing vasoconstriction and resulting in diminished tracheal edema. Rebound tracheal edema may occur several hours later as the effect of the racemic epinephrine dissipates. Because this problem is unpredictable, the child should be admitted to the hospital for observation after racemic epinephrine has been used.

The practice of treating laryngotracheobronchitis with corticosteroids is widespread, especially for hospitalized patients.[44] Oral, intramuscular, and nebulized corticosteroids have been shown to be beneficial in randomized, blinded trials.[45,46] Meta-analyses in which the efficacy of corticosteroids was evaluated suggest that corticosteroids reduce the need for endotracheal intubation or inhaled epinephrine, hasten improvement in the first 24 hours of illness, shorten the duration of hospitalization, and reduce the frequency of readmission.[37] Mixtures of 70% helium and 30% oxygen (heliox) may be beneficial in more severe cases of laryngotracheobronchitis because the characteristics of this mixture permit greater gas flow past areas of airway narrowing.[47]

Endotracheal intubation is occasionally necessary when laryngotracheobronchitis proves refractory to medical intervention. Unless merited by special circumstances, such as severe subglottic stenosis in association with laryngotracheobronchitis, tracheostomy offers no advantages over endotracheal intubation. The endotracheal tube should be smaller than would normally be used to avoid additional injury to the swollen tracheal mucosa. If the tracheal edema is severe, even a small tube may fit tightly in the trachea.

Later, when an audible leak around the endotracheal tube is present, the trachea

may be extubated with a high probability that reintubation will not be necessary.[48] If a leak does not become audible after 2 to 4 days, it is our practice to extubate the trachea, because prolonged intubation may increase the risk for subglottic injury. Racemic epinephrine is commonly needed to treat stridor after extubation. If a patient should have especially severe or recurrent laryngotracheobronchitis, an anatomic lesion causing tracheal narrowing should be suspected.

Recurrent croup is a frequently encountered problem. Physicians caring for these patients are often pressed to consider further evaluation to determine if an anatomic abnormality may be responsible for the problem. A review of the experience of rigid bronchoscopic evaluation of children with recurrent croup indicates that gastroesophageal reflux is common in these children (45%), whereas only 11% of the children had anatomic anomalies requiring surgical intervention.[49]

Epiglottitis

Epiglottitis caused by *Haemophilus influenzae* type B was once a common cause of serious respiratory illness in pediatric patients, but because of widespread use of the *H. influenzae* type B vaccine, this is now an uncommon illness in young children.[50] Patients who present with epiglottis are now older, with an average age of 11.6 years as opposed to an average age of 5.8 years before the advent of Hib vaccination.[51] Although cases of *H. influenzae* epiglottis continue to occur, even among vaccinated patients,[52] other causes of epiglottitis have assumed greater importance in the postvaccination era. Group A β-hemolytic *Streptococcus* is now identified as the cause of epiglottitis in many patients and is clinically indistinguishable from epiglottitis caused by *H. influenzae* type B.[53] Thermal injury to the epiglottis from ingesting hot liquids can also cause epiglottitis.[54] Several points serve to distinguish epiglottitis from laryngotracheobronchitis (Table 50.2).

TABLE 50.2

Characteristics of Laryngotracheobronchitis, Bacterial Tracheitis, and Epiglottitis

	Laryngotracheobronchitis	Bacterial Tracheitis	Epiglottitis
Age	3 mo to 3 yr	6 mo to 12 yr	12 yr (average)
Onset	Gradual	Intermediate	<24 hr
Fever	Usually low	Usually high	High
Cough	Characteristic “barking”	Characteristic “barking”	None
Sore throat	None	Usually absent	Often severe
Drooling	No	No	Usually
Posture	Any position	Any position	Sitting forward, mouth open, drooling
Voice	Normal	Normal or hoarse	Muffled
Appearance	Nontoxic	Toxic	Toxic
Seasonal distribution	Usually winter, epidemic	Throughout the year	Throughout the year

Although infrequently seen, the management of epiglottitis in young children is a multidisciplinary undertaking, involving pediatric intensive care specialists, anesthesiologists, and otolaryngologists. When a child with presumed epiglottitis is admitted to the emergency department, this team should be notified in anticipation of taking the child to the operating room to secure his or her airway. As the team members are being notified, lateral radiographs of the neck may be obtained if tolerated by the patient. This may be done with the child sitting on the parent's lap to minimize the child's anxiety. In epiglottitis, the anteroposterior view of the trachea

appears normal, but a lateral neck radiograph shows a markedly swollen and edematous epiglottis (Fig. 50.11). The diagnostic evaluation of the patient should proceed expeditiously, while care is taken to disturb the patient as little as possible. For this reason, fiberoptic examination of the epiglottis in the awake patient is usually not advisable. Attempts to examine the oropharynx directly or to start an intravenous line should be discouraged. The apprehension caused by these events may lead to tracheal obstruction by the enlarged epiglottis. If the patient will tolerate it, humidified oxygen should be administered, preferably through a plastic hose held by the parent.

FIG. 50.11 Lateral radiograph of the neck of a patient with epiglottitis. Note the large, swollen epiglottis *(arrow)*.

If the diagnosis of epiglottitis is strongly suspected or confirmed on the lateral neck x-ray film, the child should go to the operating room as quickly as possible. In the operating room, the patient is anesthetized with an inhaled anesthetic (sevoflurane) and oxygen while the patient is spontaneously breathing. Once the patient has been anesthetized, an intravenous catheter is inserted. Laryngoscopy is then performed (Fig. 50.12). It may be exceedingly difficult to obtain a direct view of the glottis and trachea because of the large swollen epiglottis. Nevertheless, it is almost always possible to pass an endotracheal tube through the edematous tissues and into the trachea. Nasotracheal intubation is preferred to orotracheal intubation because the tube is more readily secured to the face, the patient cannot bite the tube, and salivation is decreased. An otolaryngologist should be in the operating room and ready to do an emergency tracheostomy if an airway cannot be secured by endotracheal intubation, although this is rarely necessary. As with laryngotracheobronchitis, endotracheal intubation is preferred to tracheostomy because it has been shown that complications are more common when a

tracheostomy has been routinely used to treat epiglottitis. After the airway is secured, blood cultures and cultures of the epiglottis are obtained, and antibiotic therapy is initiated with a penicillinase-resistant antibiotic because of the high incidence of *H. influenzae* resistance to ampicillin.[55]

FIGURE 50.12 Epiglottitis causing a severely swollen epiglottis *(between the arrows)*. In the lower portion of the picture, the endotracheal tube can be seen. (Copyright Andrew F. Inglis, Jr.)

In the PICU, patients usually require endotracheal intubation for 24 to 72 hours while the swollen epiglottis returns to normal size. The patient may be allowed to breathe spontaneously through the endotracheal tube or may undergo mechanical ventilation. Variable amounts of sedation are usually necessary. Extraepiglottic sites of *H. influenzae* infection are common.

The management of epiglottitis depends on the patient's age. Adults and teenagers with epiglottitis usually present with severe pharyngitis but usually have mild or absent airway obstruction. In contrast to younger unsedated children, teenagers and adults are more likely to tolerate examination of the airway with a small fiberoptic bronchoscope. This procedure may have superior diagnostic sensitivity compared to lateral neck radiographs. Although the management of epiglottitis in young children is almost always accomplished with placement of an endotracheal tube, teenagers and adult patients may be admitted to the hospital for close observation and expectant airway management. Endotracheal intubation is reserved for patients who develop respiratory compromise.[56,57]

Peritonsillar Abscess

The initial presentation of peritonsillar abscess may resemble that of epiglottitis. The child usually has a severe sore throat and may have a muffled voice and drooling. Imaging studies such as CT scan or transcervical ultrasonography may be used to

confirm the physical findings.[58] Approximately half of the children with peritonsillar abscess are managed medically and the other half require surgical intervention, either abscess drainage or tonsillectomy.[59] Although trismus may be of concern in evaluation of the patient for anesthesia, there is usually no anatomic restriction of jaw movement. Once the patient has been anesthetized, the mouth may be easily opened. Extubation can usually be performed immediately after the abscess has been drained, unless there is severe inflammation and swelling extending well beyond the tonsillar bed. Commonly encountered microorganisms include group A *Streptococcus*[60] and *Fusobacterium* species.[61]

Retropharyngeal Abscess

Over 80% of children with retropharyngeal abscess are younger than 6 years.[62] Patients may have fever, stiff neck, sore throat, and, in severe cases, respiratory distress. During examination of the oropharynx, the posterior pharyngeal wall may be observed to bulge, but most commonly the findings are unremarkable. Palpation of the posterior pharyngeal wall should be avoided because it may cause rupture of the abscess with possible spillage of the contents into the tracheobronchial tree. The presence of torticollis is seen much more frequently when an abscess is present.[62] An inspiratory radiograph of the lateral neck may show thickening of the prevertebral soft tissue, and occasionally an air-fluid level may be present (Fig. 50.13). A chest radiograph should be obtained to evaluate possible mediastinal extension of the infection. Contrast CT scanning is commonly employed to evaluate these infections; however, evidence of abscess on CT scan does not reliably predict the quantity of purulent material obtained at the time of surgical drainage.[63]

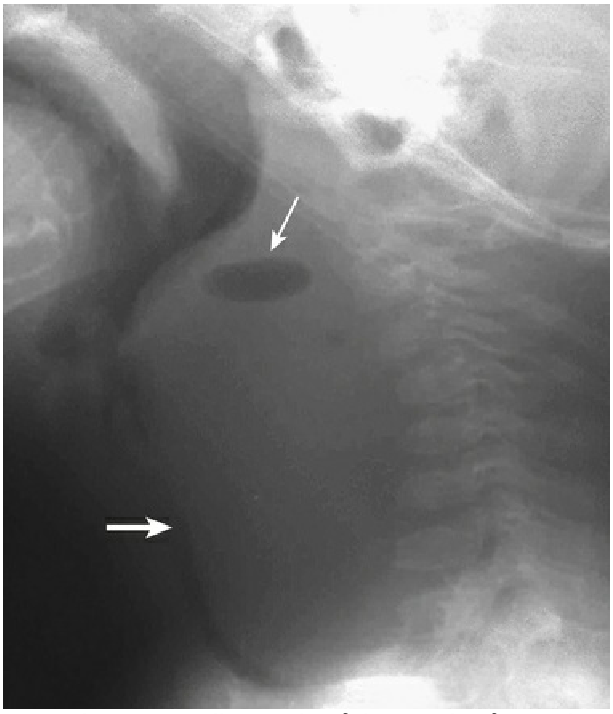

FIG. 50.13 Lateral radiograph of the neck of a patient with retropharyngeal abscess. Note the thickening of the prevertebral soft

tissue and the radiolucent area caused by the presence of air in the tissue *(arrows)*. (Copyright Andrew F. Inglis, Jr.)

Depending on the severity of the abscess, a large proportion of patients treated with antibiotic therapy can be cured without surgical intervention.[64-66] Surgical treatment of this lesion is drainage of the abscess, after the patient has been anesthetized and an endotracheal tube has been inserted to protect the patient from pulmonary aspiration of the purulent fluid.

Bacterial Tracheitis

The peak incidence of this infection occurs in the fall and winter and tends to affect children between 6 months and 8 years of age. Bacterial tracheitis is a secondary infection that begins during a viral upper respiratory infection.[67-69] Frequently, but not always, bacterial tracheitis will resemble viral laryngotracheobronchitis (croup); however, patients with bacterial tracheitis usually have a high fever and may appear very ill at the time of presentation (see Table 50.2). Unlike patients with croup, these patients show little or no response to nebulized racemic epinephrine. Bronchoscopy, which is the definitive diagnostic procedure, shows normal supraglottic structures and diffuse inflammation of the larynx, trachea, and bronchi,[70] with adherent or semiadherent purulent membranes in the trachea.[71] Endotracheal intubation is often necessary because of severe, progressive respiratory distress. Following endotracheal intubation, aggressive tracheobronchial toilet may be necessary because thick, tenacious purulent debris may rapidly occlude the endotracheal tube.

A variety of bacterial agents have been reported in association with this illness, including *Moraxella catarrhalis, Staphylococcus aureus, Haemophilus influenzae* type B, and *Pneumococcus*.[72,73] The injury to the respiratory epithelium caused by the virus may predispose the patients to bacterial superinfection. The most common complication of bacterial tracheitis is pneumonia, which is observed in approximately 60% of patients with this illness. Antibiotics are an important aspect of therapy and should be directed by the results of bacterial cultures obtained during bronchoscopy or immediately after endotracheal intubation.

Laryngeal Papillomatosis

The laryngeal papilloma is the most common benign tumor of the larynx during childhood. The agent causing this disease is human papilloma virus, with types 6 and 11 causing the majority of cases.[74] Despite its nonmalignant structure, the propensity of this tumor to cause respiratory obstruction may result in injury to the patient or death. The onset of symptoms occurs between infancy and 4 years of age. New onset of infection is less frequent after age 5 years. The most common medical complaint in these children is voice change, which occurs in more than 90% of the patients. Airway obstruction is present in almost half of the patients, although it is mild in many of these. The presence of inspiratory stridor may misdirect the diagnostician to think that the child has laryngotracheobronchitis. The diagnosis is typically made with laryngoscopy (Fig. 50.14).

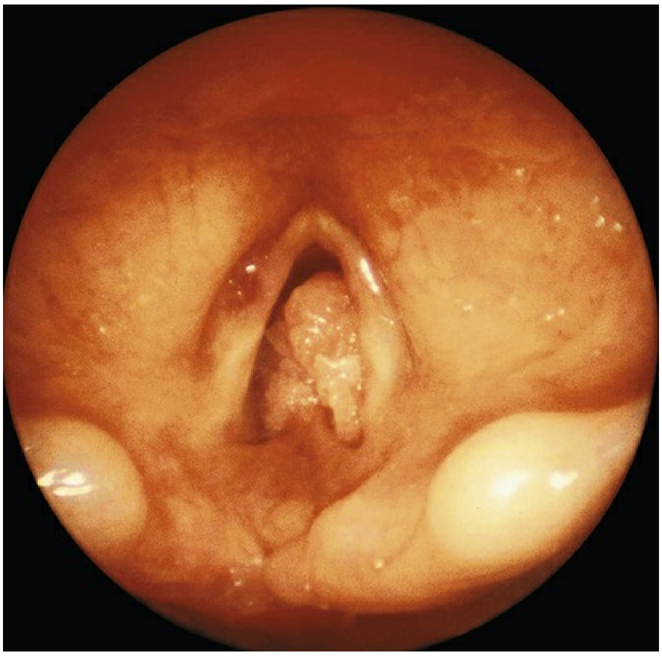

FIG. 50.14 Large, pedunculated papilloma is seen just below the vocal cords. These papillomas almost completely occluded the tracheal lumen and produced marked respiratory distress. (Copyright Andrew F. Inglis, Jr.)

The treatment for this illness is surgical excision of the polyps.[75] Induction of anesthesia in the child with severe airway obstruction may be hazardous, because it may be difficult or impossible to ventilate the child's lungs after loss of consciousness. Although patients characteristically require multiple surgical resections of these lesions (an average of 11 resections over the course of the disease), the mortality with this illness is low. Carbon dioxide laser vaporization of the papillomata is widely used. During laser excision of lesions caused by a similar viral agent, anogenital condylomas, medical personnel have become infected with the virus, presumably from viable virus particles carried in the smoke plume.[76]

A variety of adjuvant therapies have been developed to reduce the frequency of relapse following surgical treatment.[77] These adjuvant therapies include interferon-α, acyclovir, valacyclovir, and cidofovir, among others. It has been suggested that the human papillomavirus (HPV) vaccine may reduce the incidence and recurrence of laryngeal papillomatosis.[78]

Vocal Cord Paralysis

The recurrent laryngeal nerves supply the bulk of the motor innervation to the larynx. These nerves originate in the nucleus ambiguous in the brain stem, travel to the chest with the vagus nerve, and then loop back up to the larynx in the tracheoesophageal groove. The left recurrent laryngeal nerve loops under the ductus arteriosus in the chest, and thus it is vulnerable to injury during ligation of this vessel and with other thoracic vascular procedures.[79] Symptoms associated with even complete unilateral vocal cord paralysis vary greatly in severity. In infants, they may range from a mildly diminished cry to a severely disabled larynx with significant stridor, feeding difficulties from aspiration, and loss of voice.[80] Bilateral vocal cord paralysis almost always produces significant stridor with varying degrees

of airway distress.[81] Stridor in these instances is typically inspiratory and may be confused with laryngomalacia, a much more common entity. Over half of the patients have associated anomalies including concomitant airway diseases.[37,81] Diagnosis can usually be made at the bedside by fiberoptic laryngoscopy.[82]

Congenital vocal cord paralysis is usually idiopathic and often resolves spontaneously over several months. This is the most common cause of bilateral vocal cord paralysis in children.[83] Other neurologic causes, such as Arnold-Chiari malformation, are occasionally seen, and workup usually includes an MRI. The cause of acquired vocal cord paralysis is usually obvious, with most cases coming after thoracic or cervical surgery.[81,84]

The treatment of vocal cord paralysis in the critical care setting is primarily supportive. Airway support may include temporizing with high-flow nasal oxygen or continuous positive airway pressure/biphasic positive airway pressure (CPAP/BiPAP).[37] Over 60% of patients with bilateral and some with unilateral vocal cord paralysis require tracheostomy,[37,81] but procedures aimed at enlarging the glottic airway—vocal cordotomy, arytenoidectomy, vocal cord lateralization, and posterior cricoid split and cartilage grafting[82]—should be delayed, as spontaneous recovery is possible within the first 2 years.[85] If a specific lesion may be addressed medically or surgically (such as decompression of the brain stem in Arnold-Chiari malformation), such therapy should be undertaken.

Intrathoracic Mass Lesions Causing Respiratory Obstruction

The intrathoracic trachea may be compressed by a variety of anterior mediastinal masses. Because the symptoms produced by a malignant mass impinging on the trachea can worsen dramatically over several days, the child with respiratory compromise resulting from a mediastinal mass deserves rapid evaluation and aggressive medical therapy.

Before caring for a child with this problem, the parents should be asked if the child refuses to lie in certain positions. The child's reluctance to recline in a given position may be caused by airway compromise from the mass. Forcing the child to lie down may result in airway obstruction or even cardiac arrest.[86] Endotracheal intubation is indicated only if respiratory function becomes severely compromised. Unfortunately, this measure may be of little benefit, because the lesion may compress the bronchi distal to the tip of the endotracheal tube requiring advancing the endotracheal tube into the mainstem bronchi.[87] In addition, it may be impossible to ventilate the child's lungs after muscle relaxants have been administered to facilitate placement of the endotracheal tube. Mechanical support with extracorporeal membrane oxygenation (ECMO) has been used to assist patients with large mediastinal masses; however, the mass may distort the great vessels and pose unusual challenges for the ECMO team.[88] Obtaining tissue for a pathologic diagnosis can be a challenge, as these patients are at significant risk for anesthetic complications.[89,90] It is therefore recommended that the least invasive and lowest risk diagnostic intervention is employed first, when appropriate. When mediastinal biopsy under anesthesia is inevitable, preparations should be made to rapidly treat intraoperative complications by changing patient position, opening the intrathoracic

airway with rigid bronchoscopy, performing emergency thoraco/sternotomy, or implementing ECMO cannulation via the femoral vessels.[91]

Trauma

Postextubation Stridor

After endotracheal intubation that lasts more than a few hours, postextubation stridor is a relatively common problem in small children and is most frequently caused by laryngeal edema. Estimates of the frequency of postextubation stridor in children vary widely. Most authors cite figures of less than 2% to 9%,[92,93] although the incidence may be as high as 37% in patients with trauma or burns.[94]

In addition to audible stridor, patients with this problem show decreased air movement, flaring of the alae nasi, and, in more severe cases, decreased arterial oxygen saturation and mental status changes. The severity of these signs reliably indicates the severity of airway obstruction.[95]

Several risks are associated with the development of postextubation stridor. Endotracheal tube size plays an important role, because too large an endotracheal tube may compress the tracheal mucosa, causing submucosal ischemia. When the endotracheal tube is removed, the injured tissue may swell and partially obstruct the larynx. Endotracheal tube movement within the trachea may produce trauma to the tracheal mucosa, resulting in tissue injury and swelling. Whether stridor occurs depends on the extent of the swelling and the diameter of the child's airway. Small patients are more likely to have postextubation stridor because a larger proportion of their airway is obstructed with a given degree of swelling and because of the unfavorable characteristics of turbulent flow through small passages. Lack of an audible leak of air around the endotracheal tube is frequently used as a predictor of postextubation stridor in children; however, one study suggests that this measure may be valid only in children ages 7 years and older.[96]

The presence of an endotracheal tube cuff was felt to contribute to the risk of postextubation stridor in children younger than 8 years of age, where the subglottic region is the narrowest portion of the airway. More recent data, however, show that with careful monitoring of cuff pressure,[97,98] the use of endotracheal tubes with low pressure–high volume cuff is not only safe in term neonates, infants, and children[92,93,99] but, given their numerous advantages, are preferable.[100,92,93,99,93]

Postextubation stridor has a greater risk of developing in children with trisomy 21; as many as one-third of these patients have stridor after extubation. There appear to be several causes for this problem, including hypotonia and facial abnormalities, such as a large tongue.

Although most cases of postextubation stridor are caused by laryngeal edema, when this problem persists, other causes should be sought. Anatomic airway anomalies, which may not be visible during endotracheal intubation (such as tracheal hemangioma), may cause persistent postextubation stridor. Vocal cord paralysis is one of the more common causes of persistent postextubation stridor and may be caused by increased intracranial pressure, brain stem compression,[101] trauma to the brain stem after neurosurgery, or recurrent laryngeal nerve during thoracic surgery.[102]

The therapy of postextubation stridor is aimed at reducing airway edema. Racemic

epinephrine and dexamethasone are the most widely used therapeutic agents. Racemic epinephrine, delivered by aerosol nebulizer, probably works by stimulation of α-adrenergic receptors; this stimulation causes vasoconstriction, which, in turn, reduces tracheal edema. Racemic epinephrine works rapidly, so improvement, when it occurs, should be observed within a few minutes of completion of therapy. Mixtures of helium and oxygen have also proved helpful in the treatment of postextubation stridor.[103]

The practice of using dexamethasone to treat postextubation stridor is widespread,[104] although the efficacy of this therapy remains controversial. Although data from animal studies suggest that corticosteroid use at the time of extubation may reduce tracheal edema, inflammation, and capillary dilation, a meta-analysis of prior studies failed to show reduction of postextubation stridor after corticosteroid use.[105] Nevertheless, many practitioners think that dexamethasone (or an equivalent dose of another steroid) will ameliorate postextubation stridor, especially if the medication is administered several hours before extubation.

In most cases, postextubation stridor is self-limited, but occasionally, endotracheal intubation may be necessary. If the degree of airway obstruction before reintubation was severe, postobstructive pulmonary edema may be observed and should be treated with positive end-expiratory pressure. When reintubation is contemplated, the size of the previous endotracheal tube should be determined, and a smaller endotracheal tube should be selected in the hope of preventing additional tracheal injury. Ideally, the trachea should remain intubated until a leak around the endotracheal tube is observed, indicating resolution of the laryngeal edema.

Laryngotracheal (Subglottic) Stenosis

Laryngotracheal stenosis is most commonly seen as a complication of prolonged endotracheal intubation, and as such it is of special interest to the critical care practitioner (Fig. 50.15). Injury most commonly occurs in the larynx at the level of the cricoid cartilage, just below the vocal cords, the only part of the airway below the nose that is surrounded by a complete circumferential ring of cartilage. This region cannot expand under pressure and is thus more susceptible to pressure necrosis and scarring (subglottic stenosis). Airway stenosis also can occur at the level of the vocal cords (glottic stenosis) when scarring occurs within the cricoarytenoid joints (cricoarytenoid ankylosis) or between the arytenoid cartilages (interarytenoid fibrosis). Glottic stenosis prevents vocal cord abduction and occasionally may be confused with bilateral vocal cord paralysis. Rarely, tracheal stenosis may be seen as a result of endotracheal tube (ETT) cuff injury, often in the setting of infection requiring high-pressure ventilation.

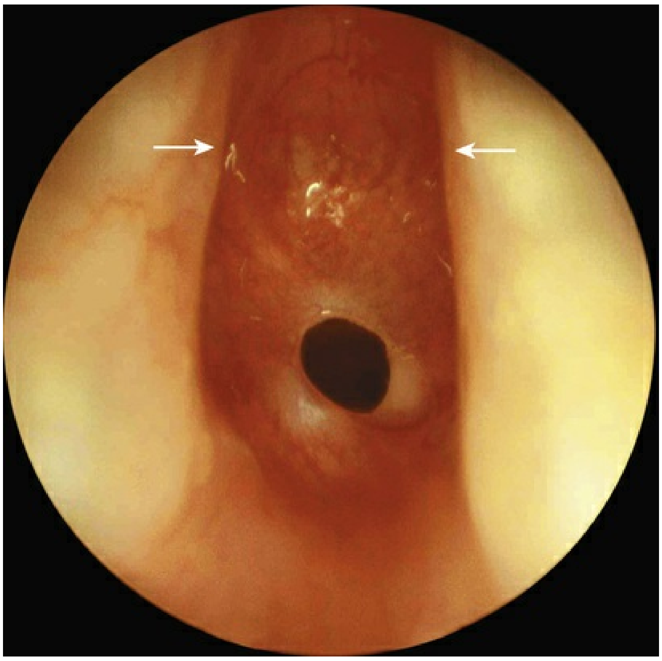

FIG. 50.15 A cicatricial ring *(between the arrows)* is demonstrated just below the glottis. This was caused by trauma from prolonged endotracheal intubation. (Copyright Andrew F. Inglis, Jr.)

Laryngeal intubation injury appears to result from an interaction of several elements, including individual susceptibility, movement of the endotracheal tube, size of the ETT, presence of infection, and duration of intubation. Fortunately, the incidence of this complication in neonates appears to be decreasing.[106] The odds of prevention will be enhanced by choosing the smallest tube that allows adequate ventilation and pulmonary care; this reduces the risk of subglottic stenosis. It is also thought that nasotracheal intubation may reduce movement of the ETT within the airway and thus diminish trauma, although this benefit comes with an increased risk of sinusitis secondary to obstruction of drainage from the sinus cavities. Gastroesophageal reflux is frequently present and perhaps plays a significant role in the development of laryngotracheal stenosis.[106] The role of early intervention with a tracheotomy for the prevention of laryngeal stenosis is controversial.[107]

Chronic laryngeal stenosis can be managed a variety of ways.[108] The obstruction may be bypassed with a tracheotomy or may be managed with high-pressure balloon dilatation, endoscopic excision of scar, cricoid expansion via cricoid split and cartilage grafts, and excision of the stenotic segment and reanastomosis via partial cricotracheal resection.[109] Postoperative management of these patients is frequently complicated by the need to allow the larynx to heal for 5 to 14 days while maintaining a patent airway with an endotracheal tube. Management of the patient during this critical period is controversial. Some favor heavy sedation including the use of neuromuscular blocking agents to minimize the chance of movement of the ETT and accidental extubation. Others favor the opposite, actually allowing the patient to be alert and active with the ETT in place.[110,111]

Ideally, reconstruction will be performed at a young age (younger than 25 months) to minimize the time period the child is exposed to the hazards of being dependent on the tracheotomy airway and so that the child's speech and language development are not impaired.[112] Earlier laryngotracheal reconstruction may, however, be more

prone to failure and require revision procedures.

Foreign Body Aspiration

Airway obstruction may be produced by aspiration of a variety of foreign bodies, with nuts, seeds, and legumes (peanuts) being the most frequent offenders in children.[113,114] Most of the patients aspirating foreign bodies are aged 1 to 3 years, with more than 95% being younger than 10 years. Fewer than 30% of patients aspirating foreign bodies receive medical attention within the first 24 hours, with many patients experiencing a significant delay before seeking medical attention.[115] Patients with an aspirated foreign body may initially be symptom-free or may have a cough, wheezing, and evidence of respiratory embarrassment. Patients without symptoms who do not seek medical attention may have a persistent cough and may develop pneumonia distal to the obstructed bronchus. Recurrent bouts of pneumonia may lead to bronchiectasis if the foreign body is not removed.

Foreign bodies may become lodged in the airway anywhere from the posterior pharynx to the bronchi. The symptoms produced by foreign body aspiration vary according to the site of the foreign body and the degree of obstruction it produces. Foreign bodies of the extrathoracic airway characteristically produce inspiratory stridor. Foreign bodies lodged in the intrathoracic trachea and bronchi tend to produce expiratory stridor and wheezing.

Radiographic evaluation should include inspiratory and expiratory radiographs because a single anteroposterior radiograph will be unremarkable in 18% of children with an aspirated foreign body (Fig. 50.16).[115] If the foreign body is producing ball-valve bronchial obstruction, hyperinflation of the involved lung will be seen during the expiratory radiogram. Many foreign bodies are not radiopaque,[116] so failure to see a foreign body on the chest radiograph cannot exclude this diagnosis. If a suspicion of an aspiration is high, a bronchoscopy is warranted (Fig. 50.17).

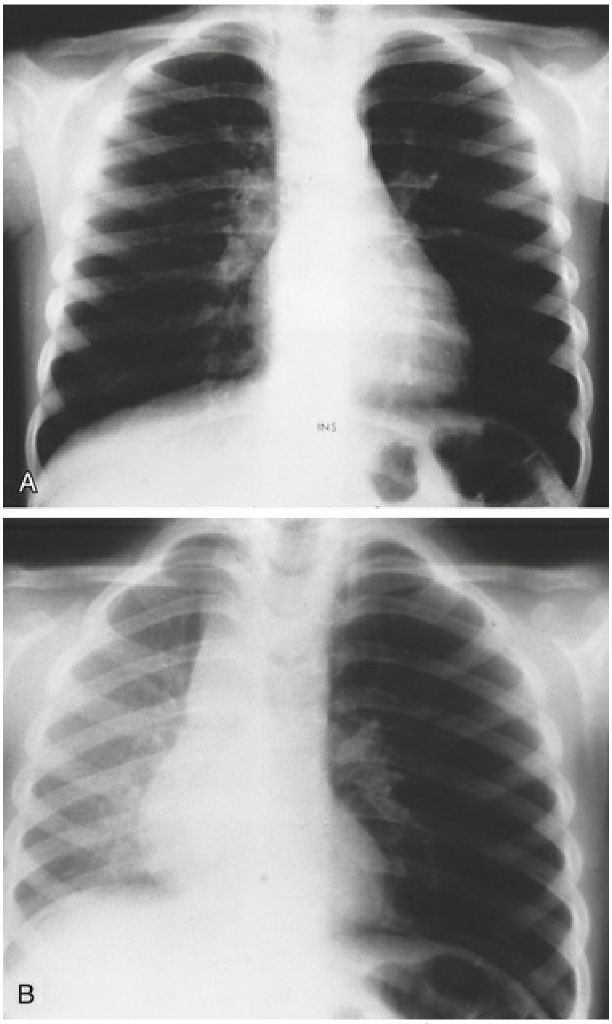

FIG. 50.16 Inspiratory chest radiograph with foreign body present in left mainstem bronchus. During inspiration (A), the left lung is slightly hyperinflated but could be considered normal. The expiratory radiograph (B) clearly demonstrates that the left lung is hyperinflated because of air trapping by the foreign body. (A and B, Courtesy Eric Effmann, MD.)

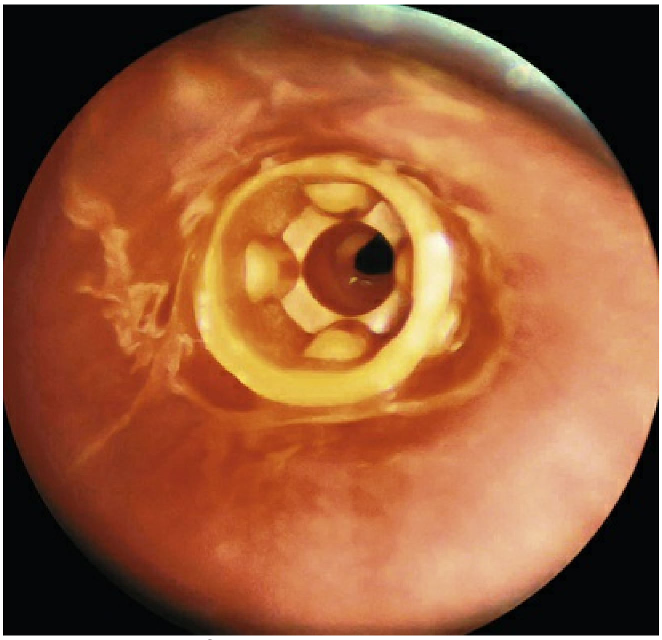

FIG. 50.17 Hollow plastic foreign body in patient's trachea. Because the object was not radiopaque, it could not be observed on a chest radiograph, and because the lumen of the foreign body was aligned with the tracheal lumen, severe respiratory embarrassment did not occur. (Copyright Andrew F. Inglis, Jr.)

Foreign bodies are removed from the tracheobronchial tree with a rigid or, less commonly, with a flexible bronchoscope.[117] Occasionally this is impossible and tracheostomy or thoracotomy for bronchotomy or lobectomy is required.[118] Cardiopulmonary bypass has been successfully used to support a patient who had extensive foreign body aspiration.

Traumatic Injury to the Airway

Traumatic injury to the upper airway may be divided into two broad categories: oral facial trauma and laryngeal/tracheal trauma. Patients with obvious oral facial trauma may be at risk for upper airway obstruction. Even if the patients have no sign of respiratory distress at the time of presentation, swelling of soft tissues and hemorrhaging to the airway may lead to airway compromise.

Patients who must undergo operative intervention to treat their traumatic injuries need careful evaluation of their airway, including radiographs and CT scan examination. Traumatic injuries may make intubations in the trachea difficult in these patients. For this reason, sedation is to be avoided and endotracheal intubation with the patient awake should be considered. This may be accomplished with direct laryngoscopy after local anesthesia has been applied to the patient's oropharynx. In more difficult cases, it may be necessary to use a fiberoptic bronchoscope to guide the ETT into the trachea.

Postoperatively, patients undergoing repair of facial trauma may have their jaw wired shut and the nasal/submental ETT sutured in place to prevent accidental extubation. These patients should undergo extubation only when fully awake and after resolution of their airway and facial edema. Instruments to open the wires should always be kept at the patient's bedside. Emesis may present a grave hazard in

these patients.

Injury to the larynx and trachea may occur after blunt trauma such as automobile accidents, after penetrating trauma, clothesline injury, or with crush injuries such as hanging. Blunt trauma to the neck may lead to fracture of the cartilaginous rings supporting the trachea or to disruption of the tracheal mucosa. In the latter case, attempted endotracheal intubation may worsen a partial tracheal transection and create an airway emergency.[119] Signs of laryngeal injury include dyspnea, altered phonation, odynophagia, hoarseness, hemoptysis, swelling, and subcutaneous emphysema of the neck. The development of subcutaneous emphysema after blunt trauma to the neck suggests that a laryngeal fracture or tracheal tear has occurred. The quantity of air in the subcutaneous tissues does not correlate with the severity of the injury.[120] Establishment of an adequate airway is an essential consideration. Although the standard of care in management used to be surgical repair, often preceded by tracheostomy placement, conservative management with prolonged endotracheal intubation is now acceptable,[121] and tracheostomy is only necessary in about one-third of cases.[122]

Blunt thoracic trauma can cause tracheal or bronchial disruption. Most commonly, these are blowout injuries that result in tracheobronchial disruption. These injuries usually occur near the carina, and most involve mainstem bronchi.[123] Because children have flexible ribs, severe intrathoracic injuries can occur without rib fractures. The signs of tracheobronchial disruption include persistent air leak, failure to expand the lung with thoracostomy tube drainage, and massive atelectasis (from failure to conduct gas through an injured bronchus). Diagnosis of these injuries is usually made with bronchoscopy. Although small tracheobronchial disruptions may be managed conservatively, most of these lesions require surgical repair.[123]

Burn Injury to the Upper Airway

Thermal injury to the upper airway may complicate the management of a patient with burns. The presence of facial burns and singed nasal hairs, hoarseness, or inspiratory stridor should suggest the possibility of burn injury to the upper airway. Although respiratory compromise may not be present at the time of admission, it may develop later as swelling of the injured airway becomes more severe. Because of the efficient cooling capacity of the upper air passages, thermal injury to the airway below the vocal cords is uncommon, occurring in less than 5% of all hospitalized patients with burns.

Evidence of respiratory embarrassment in a patient with burns should be rapidly evaluated. Neck radiographs and fiberoptic examination of the larynx may show swelling of the soft tissues of the airway. If these findings are present, endotracheal intubation should be expeditiously performed to secure the airway before obstruction occurs. Because of the risk of infection, attempts are made to avoid tracheostomy placement in the patient with burns, and data suggest this is a safe practice.[107] Upper airway embarrassment is often accompanied by smoke inhalation injury to the lower airway, resulting in hypoxemia and hypercapnia. The products of combustion result in severe carbon monoxide intoxication or cyanide poisoning, both of which have nonspecific symptoms but require prompt medical therapy.[124]

Angioedema

Angioedema is a well-demarcated localized edema involving the deep layers of skin, including the subcutaneous tissue. Angioedema may occur in response to a variety of systemic disorders, including allergic reactions that are mediated with immunoglobulin E, anaphylactic and anaphylactoid reactions, and other illnesses. Angioedema may lead to swelling of the soft tissue of the face, particularly the eyes and lips. If this should involve the soft tissues of the upper respiratory tract, laryngeal obstruction may result. Administration of subcutaneous epinephrine may dramatically reduce swelling caused by this condition. Compared to adults, children often have a rapid response to antihistamines and steroids.[125] Occasionally, respiratory embarrassment caused by this condition is so severe that endotracheal intubation is warranted. The evaluation of patients with this disorder should be directed at (1) the identification of the causative agents so that the patients can avoid these in the future and (2) the anatomic site of presentation to allow stratification of airway risk and planning of appropriate triage for airway intervention.[126]

Tracheostomy

Indications for the placement of a tracheostomy fall into three broad, frequently overlapping categories: airway obstruction, assisted ventilation, and pulmonary toilet. Pediatric anatomic anomalies that may necessitate tracheostomy are most often manifested in the neonatal period or in infancy, although some may not appear until childhood. The most common abnormalities include vocal cord paralysis (congenital and postbirth injury), subglottic stenosis, tracheal stenosis, cystic hygroma, tracheal hemangioma, and laryngeal cyst. The accurate diagnosis of these problems is frequently made during bronchoscopic examination of the larynx and trachea while the patient is anesthetized. If the obstruction is of sufficient magnitude, consideration should be given to doing a tracheotomy at the time of bronchoscopy.

Infants may require a tracheostomy because of the need for prolonged periods of assisted ventilation. The advent of neonatal intensive care has enabled small preterm infants to survive despite severe respiratory illness. Many of these patients will need lengthy periods of mechanical ventilation to treat infant respiratory distress syndrome and bronchopulmonary dysplasia. Prolonged intubation may lead to subglottic stenosis.[127] For a reduction in the frequency of this complication, a tracheostomy may be performed. The optimal timing of tracheostomy for children who need long-term intubation is controversial. In many neonatal ICUs, infants needing mechanical ventilatory support for more than 30 to 45 days will undergo a tracheostomy. Placement of a tracheostomy is not a trivial matter, with several large studies showing a tracheostomy-related mortality rate of 0.5% to 0.7%.[128,129] One study provided evidence that long-term tracheostomy is associated with airway inflammation (number of cells, neutrophils), more frequent bacteria, and reduced concentration of surfactant protein-D.[130] The decline of polio in the United States during the decade following 1950 dramatically decreased the number of tracheostomies performed to facilitate mechanical ventilation and pulmonary toilet. Nevertheless, several pediatric diseases predictably lead to prolonged neuromuscular failure. Infants with infant botulism may have prolonged neuromuscular weakness and may undergo a tracheostomy to simplify management

of mechanical ventilation. Similarly, older children with Guillain-Barré syndrome and respiratory failure may need a tracheostomy if a lengthy course of mechanical ventilation is expected. The use of tracheostomy has been advocated to promote pulmonary toilet and improve ventilation during the treatment of flail chest.

The timing of the tracheostomy will depend on several issues, including the patient's underlying illness and the severity of the condition that makes tracheostomy necessary. If possible, emergency tracheostomy under unfavorable conditions should be avoided because the complications are more common in this setting. Percutaneous placement of a tracheostomy has been widely used in the adult population; however, experience in children remains limited. One small retrospective series suggests that placement in the ICU can be done safely with adherence to sound techniques and prudent patient selection.[131]

Postoperative Nursing Care

Care from attentive, trained nurses is essential for the well-being of the patient with a tracheostomy. Until a tract of granulation tissue has formed in the stoma between the cervical and tracheal epithelium, precautions should be taken to prevent the accidental displacement of the tracheostomy tube. Although stay sutures simplify replacement of the tracheostomy tube, this procedure may be difficult, especially in an emergency situation with a struggling patient. A hastily replaced tube may be incorrectly located in the pretracheal soft tissue, resulting in asphyxiation. If positive pressure ventilation is attempted with the tube in this position, subcutaneous and mediastinal emphysema may be followed by a life-threatening tension pneumothorax. Because of these risks, patients routinely stay in the ICU for 5 to 7 days postoperatively. Smaller children have arm restraints placed to prevent them from pulling at the tracheostomy tube. If necessary, sedation is given until the child grows accustomed to the tracheostomy and the tract matures with the formation of granulation tissue. If accidental displacement of the tracheostomy tube does occur, replacement may be facilitated with a gentle insertion of a 0 Miller laryngoscope blade into the stoma and the identification of the tracheal lumen before the tube is passed.

Besides avoiding accidental displacement of the tracheostomy, the nurse must constantly monitor the patient for obstruction of the tracheostomy tube. The tube may be obstructed by dried tracheal mucus. Sometimes the patient's chin may obstruct the tube. Humidified gas may be administered to prevent drying and inspissation of secretions.

Complications

Any operation on the airway involves risk. The complication rate after tracheostomy has been reported to be 10% to 30%, with a death rate of 3%. Early postoperative complications include air leak, hemorrhage, and aspiration. Air leak is seen more often in children than in adults and may be life threatening. The risk of complications declines as the patient ages. Some life-threatening complications, such as accidental decannulation or tracheostomy tube obstruction, may occur anytime after the placement of a tracheostomy. The safety and well-being of patients with a

tracheostomy require constant vigilance to prevent these mishaps.

Swallowing dysfunction after tracheostomy may lead to aspiration of saliva and food. This may be due in part to anchoring of the trachea to the skin of the neck, preventing the cephalad movement of the trachea during swallowing. Children who have a tracheostomy often have difficulty learning to eat. The high frequency of pneumonia observed after tracheostomy may be in part due to the problem of recurrent aspiration. Aerophagia, another form of swallowing dysfunction, occurs with modest frequency in pediatric patients after tracheostomy.

Late complications include granulation tissue formation, tracheal stenosis, infection of the stoma, pneumonia, fused vocal cords, and distal tracheomalacia. Although infection of the stoma and distal tracheomalacia may be evident before decannulation, granulation formation and fused vocal cords may not be apparent until decannulation is attempted. An uncommon but particularly dangerous late complication is erosion of the tracheostomy tube into the innominate artery.

Decannulation

Problems at the time of decannulation occur in up to 36% of children. These difficulties are most frequent in patients younger than 1 year. Structural abnormalities that result in decannulation problems include subglottic stenosis, tracheomalacia at the tracheostomy site, granuloma tissue obstructing the trachea, and fused vocal cords. If respiratory distress is encountered during decannulation, it should not be attributed to the patient's psychological dependence on the tracheostomy tube. Evaluation of the airway with bronchoscopy or a lateral neck radiograph is important. Psychological factors should not be considered until structural causes of respiratory embarrassment have been eliminated.

CHAPTER 51

Pediatric Acute Respiratory Distress Syndrome

Lincoln S. Smith, Robinder G. Khemani

PEARLS

- The acute respiratory distress syndrome (ARDS) is a restrictive lung disease with clinical manifestations of hypoxemia, poor respiratory system compliance (high work of breathing), and new pulmonary infiltrates. Pathologically ARDS is characterized by diffuse alveolar damage, pulmonary edema and atelectasis, and the presence of alveolar neutrophils.
- Direct insults leading to ARDS include pneumonia, gastric content aspiration, lung contusion, hydrocarbon ingestion, smoke inhalation, and mechanical ventilation. Indirect insults include sepsis, severe trauma and burn, blood transfusions, pancreatitis, major surgery, and ischemia-reperfusion injury.
- Injury to the alveolar epithelium or endothelium results in loss of the alveolar epithelial-endothelial barrier function with resultant accumulation of proteinaceous fluid in the alveolar space and surfactant inactivation.
- Cellular and soluble mediators of inflammation, surfactant inactivation and loss, coagulation dysfunction, alveolar fluid clearance, and apoptosis are pathobiological mechanisms of lung injury.
- Ventilator management for children with ARDS should embrace limiting both tidal volume (V_T) and inspiratory pressure, allowing for permissive hypercarbia with sufficient levels of positive end-expiratory pressure to prevent alveolar derecruitment and limit high concentrations of inspired fraction of oxygen.
- There is not clear evidence to support the routine use of pulmonary or nonpulmonary ancillary therapies for children with PARDS, including surfactant and iNO, but data supporting prone positioning are growing.

Introduction

The terms *wet lung, Da Nang lung,* and *shock lung* were used from the 1940s through the 1960s to describe patients who died from severe hypoxia and had diffuse pulmonary edema.[1] In 1967 Ashbaugh and colleagues described a case series of patients with severe acute hypoxemic respiratory failure, poor lung compliance, and diffuse alveolar infiltrates on chest x-ray. Although there was an 11-year-old among the 12 patients in the case series, they coined the term *acute respiratory distress syndrome in adults*, which they later called *adult respiratory distress syndrome*.[2,3] Acknowledgment that this disease process also occurred in children did not come until the 1994 American-European Consensus Conference, where it was renamed *acute respiratory distress syndrome (ARDS)*.[4,5]

Clinical Features: Pathophysiology

ARDS is characterized by the rapid onset of respiratory failure in patients with severe pulmonary or systemic inflammation (Table 51.1). ARDS is a restrictive lung disease (reduced respiratory system compliance) due to pulmonary edema, atelectasis, pulmonary consolidation, surfactant dysfunction, and chest wall restriction (chest wall edema, ascites, peritonitis, etc.). Hypoxemia results from intrapulmonary shunt ($V/Q = 0$) and $V/Q < 1$ due to heterogeneous pulmonary edema and endexpiratory lung volumes falling below functional residual capacity (FRC). Furthermore, increased physiologic dead space ($V/Q > 1$) is also common in ARDS from endothelial injury and coagulation, impaired cardiac output or pulmonary perfusion, and regional overdistension.

TABLE 51.1

Acute Respiratory Distress Syndrome Risk Factors

Direct	Indirect
Pulmonary infections	Sepsis
Inhalations	Multiple trauma
Pulmonary contusions	Blood transfusion
Aspiration	Severe burns
Mechanical ventilation	Pancreatitis
	Major surgery
	Ischemia-reperfusion injury

Chest imaging shows patchy, asymmetric to diffuse infiltrates. In patients for whom the syndrome does not resolve, persistent hypoxemia and low lung compliance persists, but increased alveolar dead space worsens. In these patients, chest imaging begins to show linear opacities and formation of bullae, and pneumothoraces may develop.

Definition

The Berlin Definition of ARDS was published in 2012, and it addressed perceived limitations of the American European Consensus Conference (AECC) definition.[6,7] Validation of the Berlin definition in pediatrics was limited by differences in the epidemiology and management of children with ARDS as compared with adults.[8,9] The Pediatric Acute Lung Injury Consensus Conference was convened to develop a pediatric definition of ARDS (Fig. 51.1).[10-12] Major differences between the Berlin and

the Pediatric Acute Lung Injury Consensus Conference (PALICC) definitions are as follows:

1. The PALICC definition does not require bilateral infiltrates on chest x-ray.

2. The PALICC definition allows substitution of SpO_2 when PaO_2 is not available to assess hypoxemia severity, providing SpO_2 ≤97%.

3. The PALICC definition introduces the use of oxygenation index (OI) or oxygenation-saturation index (OSI) to stratify severity groups.

The PALICC definition of pediatric ARDS (PARDS)[11,12] identifies an at-risk group and criteria to identify PARDS patients with chronic lung disease, cyanotic heart disease, or left ventricular dysfunction.

Age	Exclude patients with perinatalrelated lung disease			
Timing	Within 7 days of known clinical insult			
Origin of edema	Respiratory failure not fully explained by cardiac failure or fluid overload			
Chest imaging	Chest imaging findings of new infiltrate(s) consistent with acute pulmonary parenchymal disease			
Oxygenation	**Noninvasive mechanical ventilation**	**Invasive mechanical ventilation**		
	PARDS (no severity stratification)	Mild	Moderate	Severe
	Full face mask bilevel ventilation or CPAP ≥5 cm H_2O[2] PF ratio ≤300 SF ratio ≤264[1]	4≤ OI <8 5≤ OSI <7.5[1]	8≤ OI <16 7.5≤ OSI <12.3[1]	OI ≥16 OSI ≥12.3[1]
Special populations				
Cyanotic heart disease	Standard criteria above for age, timing, origin of edema, and chest imaging with an acute deterioration in oxygenation not explained by underlying cardiac disease.[3]			
Chronic lung disease	Standard criteria above for age, timing, and origin of edema with chest imaging consistent with new infiltrate and acute deterioration in oxygenation from baseline that meet oxygenation criteria above.[3]			
Left ventricular dysfunction	Standard criteria for age, timing, and origin of edema with chest imaging changes consistent with new infiltrate and acute deterioration in oxygenation that meet criteria above not explained by left ventricular dysfunction.			

FIG. 51.1 Pediatric acute respiratory distress syndrome (PARDS) definition. [1]Use PaO2-based metric when available. If PaO2 is not available, wean FIO2 to maintain SpO2 ≤97% to calculate oxygen saturation index (OSI; [FIO2× mean airway pressure × 100]/SpO2) or SpO2:FIO2 (SF) ratio. [2]For nonintubated patients treated with supplemental oxygen or nasal modes of noninvasive ventilation, see Fig. 51.2 for at-risk criteria. [3]Acute respiratory distress syndrome severity groups stratified by oxygenation index (OI; [FIO2 × mean airway pressure × 100]/PaO2) or OSI should not be applied to children with chronic lung disease who normally receive invasive mechanical ventilation or children with cyanotic congenital heart disease. *CPAP*, continuous positive airway pressure; *PF*, PaO2:FIO2.

Pathobiology

The primary pathologic description of ARDS is disruption of alveolar epithelial-endothelial barrier resulting in noncardiogenic pulmonary edema. Disruption of

surfactant and alveolar fluid clearance, dysregulated inflammation, and coagulopathy are pathobiologic mechanisms associated with worse lung injury (Fig. 51.2).[13] Etiologies associated with ARDS can be divided into direct (alveolar epithelial) and indirect (alveolar capillary) injuries (see Table 51.1). There are three conceptual phases of ARDS (acute, fibrosing, and resolution), which have substantial temporal overlap but different pathobiological mechanisms and pathology.[14]

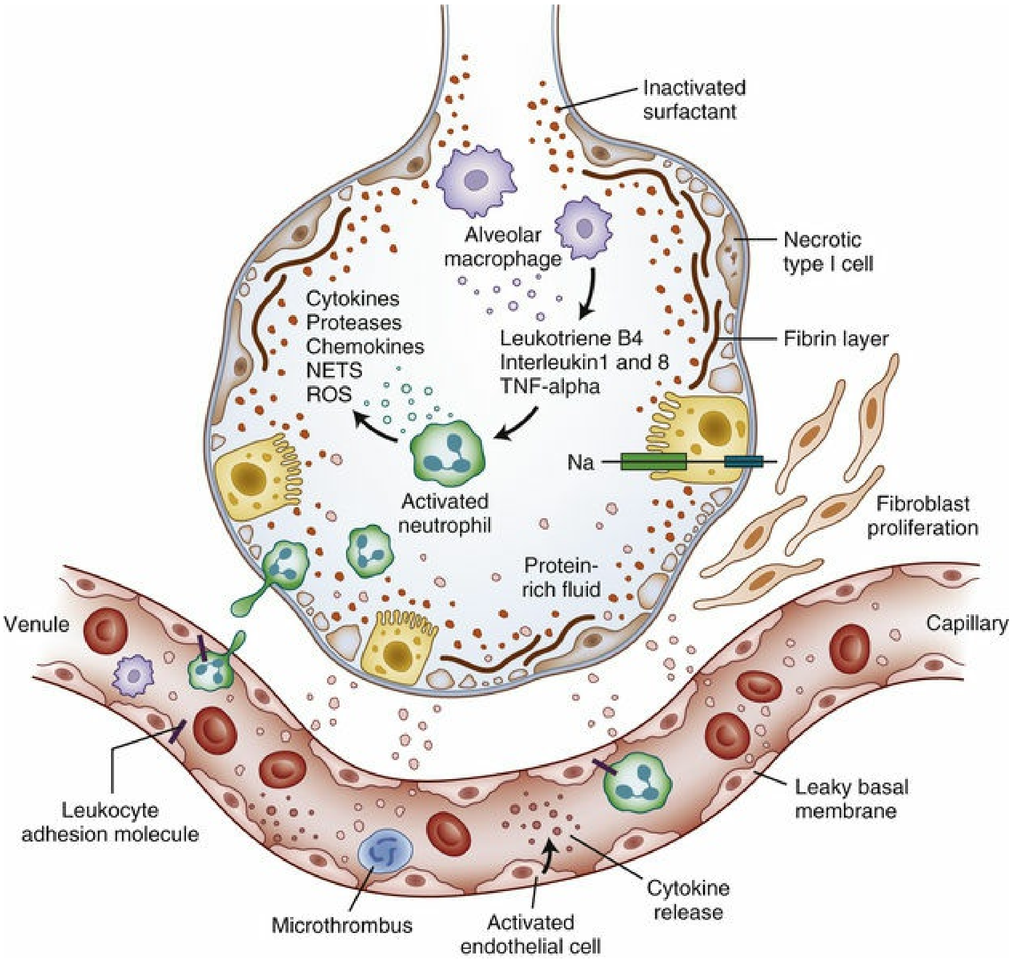

FIG. 51.2 Schematic of pathophysiology in acute respiratory distress syndrome. There is a loss of epithelial and endothelial barrier integrity and loss of function leading to increased permeability pulmonary edema. Solutes and large molecules such as albumin enter the alveolar space. In the presence of proinflammatory mediators and activated endothelium, leukocytes traffic into the pulmonary interstitium and alveoli. There is activation of coagulation and deposition of fibrin in capillaries and alveoli with increased concentrations of fibrinogen and fibrin-degradation products in the edema fluid. Surfactant depletion and degradation result in large increases in surface tension and loss of alveolar shape and integrity. Recovery is preceded by fibroblast proliferation. *NETs,* neutrophil extracellular traps; *ROS,* reactive oxygen species; *TNF,* tumor necrosis factor.

Alveolar Epithelial-Endothelial Barrier

The large surface area and thin structure of the lung is efficient for gas exchange but makes it susceptible to injury. The integrity of the alveolar epithelial-endothelial barrier requires maintenance of a thin layer of alveolar wall liquid (AWL) coating the alveolar epithelium. The AWL is necessary for dispersion of surfactant, and it is dependent on regulated flow of water, proteins, and small solutes across postcapillary venules into the alveolar airspace.[15] Excess alveolar fluid is removed by sodium-dependent transport by type II alveolar epithelial cells.[16]

Direct injuries to the alveolar epithelium causing disruption of alveolar fluid clearance (AFC) lead to pulmonary edema. Indirect injuries that increase endothelial permeability can overwhelm intact AFC, again resulting in pulmonary edema. Accumulation of pulmonary edema fluid is a cause of reduced respiratory system compliance and impaired gas exchange (ventilation/perfusion mismatch and shunt). The rate of AFC has been associated with mortality in adult patients with ARDS.[17] Catecholamines, glucocorticoids, growth factors, thyroid hormone, and Fas/FasL affect AFC,[16,18] although therapies targeting AFC have not thus far improved outcomes in adults with ARDS.[19] Regulation of postnatal lung development may be a protective factor in children with ARDS, in part through preservation of AFC.[20]

Pulmonary Endothelial Injury

Mechanical, chemical, and cellular injuries to the pulmonary endothelium cause alveolar barrier dysfunction, activate inflammatory and coagulation cascades, change pulmonary vascular resistance, and may lead to multiorgan dysfunction.[21,22] Elevated pulmonary vascular resistance and thrombosis of pulmonary capillary beds can increase alveolar dead space. Thrombomodulin is shed during endothelial injury, which has been associated with mortality in children and adults with ARDS.[23,24] Activation of the pulmonary endothelium results in increased permeability by both para- and transcellular pathways.[25] Studies of endothelial and platelet activation and coagulation in cardiovascular disease and sepsis led to a single-blinded randomized trial of recombinant human-activated protein C in adult patients with ARDS, but it did not change outcome.[26] Von Willebrand factor (vWF) has correlated with ARDS mortality in children and adults, but studies investigating other biomarkers of endothelial activation and coagulation have not consistently correlated with disease severity.[13,22] Neutrophil reactive oxygen species, supplemental oxygen, and altered endothelial nitric oxide signaling may contribute to elevated pulmonary vascular resistance. Pulmonary endothelial angiotensin-converting enzyme (ACE) and ACE2 genetic polymorphisms and activity correlate with mortality in children and adults with ARDS.[13,27] ACE and ACE2 are other mechanisms by which pulmonary endothelial biology, pulmonary vascular resistance, inflammation, apoptosis, and coagulation may intersect in the pathobiology of ARDS.[28]

Leukocytes and Inflammation

Macrophages are the only resident leukocyte in the quiescent alveolar airspace. Leukocyte infiltration into the alveolar airspace is a pathologic hallmark of ARDS.[29] The alveolar epithelium, endothelium, and activated leukocytes contribute to local and systemic inflammation. The inflammatory response is crucial to the early

response to direct injury to the lungs, but it contributes to reduced lung compliance and V/Q mismatch.

Severe systemic inflammation (high levels of circulating cytokines and chemokines) activates the alveolar endothelium and circulating leukocytes resulting in indirect lung injury. In addition to alveolar fluid accumulation, the cell surface adhesion molecules adherent to activated alveolar endothelium regulate neutrophil rolling, binding, activation, and migration into the alveolar space by both para and transcellular mechanisms.[13,30,31]

Apoptosis

Increased alveolar epithelial cell apoptosis is associated with severity of lung injury and mortality in adults with ARDS.[32,33] Nuclear factor kappa-B (NFκB)–dependent innate immune signaling via Toll-like receptors results in apoptotic signaling.[34,35] Studies also suggest that Fas ligand, transforming growth factor β (TGF-β), and lipopolysaccharide mediate inflammation, alveolar fluid clearance, and apoptosis of epithelial and endothelial cells in the lungs.[18,36-45]

Apoptosis is important for normal postnatal lung development.[46-48] Intersections between postnatal lung morphogenesis, inflammation, alveolar fluid clearance, and apoptosis may affect the outcome of children with lung injury.[20,49] Fas has been shown to mediate apoptosis in normal lung development, and Fas/FasL may protect against hyperoxic lung injury in newborn mice.[50,51] Fibroblast growth factor 10 (FGF-10) regulates postnatal lung morphogenesis and appears to reduce DNA damage and apoptosis of alveolar epithelial cells treated with cyclic mechanical stretch.[52] However, other animal studies suggest that mechanical ventilation during infancy may increase apoptosis in the lungs of newborns, thereby disrupting normal postnatal lung development.[53] Age-dependent mechanisms of apoptosis in the lungs of patients with ARDS remain an important area for future research.

Surfactant

Primary functions of surfactant are to provide variable surface tension at the air-liquid interface of the alveoli and to contribute to innate immunity.[54] The surfactant proteins B (SP-B) and C (SP-C) are hydrophobic and contribute to lowering the surface tension of the alveolar wall liquid. The surfactant proteins A (SP-A) and D (SP-D) are collectins and have important roles in innate immune responses to microbial pathogens. All four of the surfactant proteins have immunomodulatory effects and affect pulmonary fibrosis and lung remodeling.[55,56]

Adults with ARDS have low levels of SP-A, B, and D in bronchoalveolar lavage (BAL) fluid, and increased serum levels of these proteins in children and adults are associated with severity of lung injury.[57-61] There are lower levels of phospholipids in BAL fluid, as well as changes in the overall composition of the phospholipids present in BAL fluid of patients with ARDS.[62] Reactive oxygen species from high concentrations of supplemental oxygen and activated neutrophils in the alveolar spaces of patients with ARDS may cause surfactant dysfunction.[63,64] Finally, patients with genetic polymorphisms within the surfactant protein B genes that result in lower levels of SP-B have a higher risk of developing ARDS or have more severe lung injury when they become ill.[65-67] Similar findings are also seen with SP-A and D

with regard to the development of ARDS for adults with pneumonia.[68]

Coagulation

Endothelial function, inflammation, and coagulation are inextricably linked.[69,70] Activation or injury to the endothelium results in expression of tissue factor (TF) and von Willebrand factor (vWF) antigen, and vWF has been associated with mortality in pediatric and adult ARDS patients.[71,72] Plasminogen activator inhibitor-1 (PAI-1) has also been associated with severity of illness and mortality in adult and pediatric patients with ARDS.[13,73,74] Coagulopathy and fibrinolysis are not isolated to the vascular space in the lungs of patients with ARDS, as activated protein C, thrombomodulin, and TF activity have been found in the alveolar compartment and associated with alveolar epithelial cell function.[13,73,75]

Fibrosis and Repair

The acute proinflammatory response is essential to recover from direct lung injury. However, unnecessarily prolonged inflammation in the lungs can be pathologic and lead to pulmonary fibrosis. Coordination of a balanced pro-and antiinflammatory response that results in appropriate resolution of inflammation once the inciting injury has resolved requires soluble mediators, cellular immunity, and likely stem cells.

Neutrophil apoptosis is important for resolution of lung inflammation.[33,76,77] This likely begins with a coordinated response between Treg cells and macrophage subpopulations.[78-81] Although cell-cell interactions play important roles in the resolution of inflammation,[82] soluble mediators (interleukin-10 [IL-10], granzyme B, and lipid mediators) are also required.[83-85]

Multipotent mesenchymal stem (stromal) cells (MSCs) may be important to the resolution of lung inflammation and repair. In experimental models of acute lung injury, MSCs appear to modulate inflammation, augment tissue repair, enhance pathogen clearance, and reduce severity of injury, pulmonary dysfunction, and death.[86] Many of these effects occur without engraftment but rather by paracrine effects.[87] A fixed pool of MSCs in postnatal lungs that are depleted with age may be a mechanism for age-dependent differences in outcomes of patients with ARDS.

Ventilator Management

Adult and animal data support ventilator strategies in ARDS that limit tidal stretch of the alveoli (avoiding volutrauma), limit inspiratory (driving) pressure (barotrauma), allow permissive hypoxemia and hypercapnia, and provide adequate positive end-expiratory pressure (PEEP) to maintain end expiratory lung volume to limit cyclic opening and closing of the alveoli (Chapter 52). Theoretic constructs of ventilator management in ARDS advocate ventilation in a safe zone characterized by location on the deflation limb of quasi-static pressure-volume curve, in the zone of optimal compliance. Adequate PEEP during conventional ventilation or mean airway pressure during high-frequency ventilation may prevent atelectrauma by limiting cyclic opening and closing of alveoli. Limiting tidal stretch (by limiting tidal volume or peak inspiratory pressure) prevents overdistention, particularly of

relatively spared alveoli with longer inspiratory time constants.

Despite these theoretic constructs, there is limited high-level pediatric evidence regarding the optimal methods or targets to achieve these strategies.

Considerations for Ventilator Mode

There is limited evidence to support the belief that one mode of ventilation is superior to another for PARDS,[88,89] but volume control (constant flow pattern) used in the ARDS Network ARMA trial in adults is infrequently used in pediatrics in favor of a decelerating flow pattern of pressure-controlled or pressure-regulated volume control (PRVC).[90] This factor, among others, may limit the direct applicability of adult ARDS data to pediatrics. However, regardless of the mode of ventilation, the principles of lung protective ventilation are applicable and should be used for children with ARDS (Chapter 52).

Tidal Volume

Targeted tidal volume (V_T) of 6 mL/kg ideal body weight (IBW) is an evidence-based standard in adult ARDS, but pediatric data are not conclusive. Observational pediatric studies demonstrate lower mortality for patients treated with higher V_T = 6 to 10 mL/kg.[91] This is likely due to V_T commonly being the response versus the set variable in pediatric mechanical ventilation. Higher V_T for a set pressure represents better respiratory system compliance, implying the patient is less ill. Location of measurement of V_T (proximal airway versus at the ventilator without compensation for ventilator tubing compliance), IBW versus actual body weight, and correction for leak around endotracheal tubes are practice differences between adult and pediatric ICU providers that complicate extrapolation of adult V_T data to children.[92] Nevertheless, current recommendations are to use V_T in or below the physiologic range (5–8 mL/kg) IBW, with lower V_T targets in children with more compromised respiratory system compliance.[93]

Peak or Plateau Pressure

There are few data to support limit for peak or plateau pressure in pediatrics. These terms are commonly interchanged when pressure-controlled ventilation is used. There may be few differences between peak and plateau pressure for children with ARDS managed with the decelerating flow pattern of pressure-controlled ventilation, unless they concurrently have significant lower airway disease. Measuring plateau pressure requires a period of no flow during inspiration (an inspiratory hold). This maneuver may not be implemented routinely or consistently in pediatric critical care, and *plateau* pressure is often mislabeled. However, recommendations are to limit plateau pressure to 28 cm H_2O for children with normal chest wall compliance, allowing slightly higher pressures when chest wall compliance is reduced.[93] Ultimately, the shear stress induced by positive pressure ventilation is a function of transpulmonary pressure (alveolar pressure minus pleural pressure), affording the use of higher inspiratory pressure when pleural pressure is also increased (obesity). Tidal volume gets the most attention, but the ARDSNet lung protective 6 mL/kg strategy recommends decreasing V_T below 6

mL/kg if needed to limit plateau pressure to 30 cm H_2O (ARDSNet ARMA). High driving pressure (delta P), independent of both plateau pressure and V_T, is associated with higher mortality in adults with ARDS.[94]

Positive End-Expiratory Pressure

PEEP should be set to prevent lung collapse and recruitment-derecruitment injury during tidal ventilation. Unfortunately, given the inhomogeneity of lung disease in PARDS, it is difficult to use this principle to guide specific PEEP recommendations for individual patients. The optimal method to set PEEP for an individual patient remains a research question, and existing data do not support a single PEEP level (high or low) that improves outcome for adults or children with ARDS. Pediatric practice appears highly variable with respect to PEEP application, and PEEP is uncommonly increased to levels frequently used in adults with ARDS.[95,96] Adult studies that protocolize PEEP and FiO_2 for oxygenation targets support higher levels of PEEP.[97,98] Evidence is lacking in children, but moderately elevated levels of PEEP (10–15 cm H_2O) titrated to oxygenation and hemodynamic responses are recommended for children with severe PARDS, with the potential for higher levels of PEEP in the most severe patients.[93] Importantly, plateau pressure should still be limited, and markers of oxygen delivery, respiratory system compliance, and hemodynamics should be closely monitored as PEEP is increased.

Unconventional Ventilation Strategies

Various forms of unconventional ventilation are considered for children with PARDS, particularly those with severe disease. The most common unconventional mode is high-frequency oscillatory ventilation (HFOV). Although many practitioners use HFOV in PARDS, there are no data supporting improved outcomes; albeit there are data suggesting improved gas exchange. As such, HFOV is frequently used as a rescue ventilator mode. The concept of HFOV is to ventilate with V_T approximating anatomic dead space, leading many to believe it is an optimal form of lung protective ventilation and should be considered earlier in the course of ARDS. However, adult and observational pediatric data do not support use of HFOV early in ARDS.[99-102] Current recommendations are to consider HFOV for patients with moderate to severe ARDS when adequate gas exchange cannot be maintained without exceeding suggested limits of plateau pressure (ie, lung protection is not maintained with conventional ventilation).[93]

Alternative modes of unconventional ventilation such as airway pressure release ventilation (APRV) and high-frequency jet ventilation (HFJV) have some theoretic advantages for patients with moderate to severe ARDS, but there are no controlled data demonstrating that these are superior to conventional modes of ventilation or HFOV for children with PARDS.

Pulmonary Ancillary Therapies

Exogenous Surfactant

The efficacy of exogenous surfactant for PARDS may depend on the concentration of individual surfactant proteins as well as other phospholipids.[103] Investigations have

used exogenous surfactant preparations rich in either surfactant protein B or C, given their direct properties on alveolar surface tension.[104-106]

Preclinical or Adult Data

Lung injury studies in animals suggest exogenous surfactant improves oxygenation, pulmonary compliance, alveolar edema, total lung water, and alveolar protein concentrations and may have an effect on lung inflammation.[107-111]

Heterogeneous patient populations and study designs make interpreting adult data difficult. Exogenous surfactant appears to transiently improve oxygenation without affecting mortality, but some studies suggest harm related to adverse events such as hypoxemia (7%-50%), hypotension (9%-35%), transient airway obstruction, or rare events like bradycardia, leukopenia, air leak syndrome and pneumonia.[104,112-117] Posthoc analyses suggesting that treatment with recombinant protein-C surfactant benefited the subgroups of adults with ARDS direct injury were not confirmed in randomized trials.[104,118-120]

Pediatric Data

Early pediatric studies of exogenous surfactant for ARDS showed improvements in oxygenation and suggested reduced duration of ventilation and reduced mortality.[121] Unfortunately, subsequent multicenter, randomized, placebo-controlled, blinded trials of calfactant did not show improved mortality or ventilator-free days.[106,114]

A phase II placebo-controlled, double-blind, randomized controlled trial (RCT) of a synthetic surfactant preparation (lucinactant), which mimics the actions of surfactant protein B, was performed in 165 non-premature children with persistent hypoxemia.[105] The most common diagnoses were bronchiolitis and pneumonia, and only 37 children met the criteria for ARDS. Lucinactant was shown to be safe, it improved oxygenation without an effect on the duration of mechanical ventilation, and mortality was extremely low (<5%).

In summary, there is not evidence to suggest that exogenous surfactant reduces mortality for children or adults with ARDS. Exogenous surfactant can be safely administered in children, and oxygenation may transiently improve. The effects of surfactant seem to be confounded by the dosing regimen, drug delivery, drug concentration, surfactant formulation, degree of lung recruitment, lung disease severity, etiology of ARDS, comorbidities, and a multitude of other factors. Future research is warranted to identify whether subgroups of patients benefit from exogenous surfactant.

Nitric Oxide

Physiologic Rationale

Nitric oxide (NO) is normally synthesized in the vascular endothelium, causing vasodilation by relaxing smooth muscle via intracellular cyclic guanosine monophosphate (cGMP). Nitric oxide also affects inflammation by altering endothelial interactions with leucocytes and platelets.

Because inhaled NO (iNO) is theoretically delivered only to ventilated lung units, its major effect is improved V/Q balance by increasing blood flow to ventilated units, thereby reducing physiologic dead space and improving oxygenation.[122,123] iNO may

also be important for lowering pulmonary vascular resistance and supporting the right ventricle in some ARDS patients with preexisting pulmonary hypertension.[124-129]

Preclinical and Adult Studies

In addition to effects on pulmonary vascular resistance, animal data suggest iNO may both aggravate and ameliorate lung injury. Some lung injury models suggest iNO reduces neutrophil migration and oxidative burst,[130] decreases lung inflammation,[131-133] decreases platelet aggregation,[134-136] and promotes lung repair.[137] iNO may improve pulmonary bacterial clearance through mechanisms related to endothelial permeability.[138,139] Other models suggest that iNO has no effect[140] or may potentiate lung injury through proinflammatory mechanisms.[141-143]

Meta-analyses of iNO for adults with ARDS suggest that iNO does not reduce mortality.[144,145] Most studies demonstrate transient improvements in oxygenation within the first 24 hours, but there may be an increased risk of renal impairment (RR 1.59, 95% CI 1.17-2.16) among adults treated with iNO as compared with controls. However, there appears to be persistent use of iNO as a rescue therapy.[146]

Pediatric Data

There have been a number of uncontrolled trials and small RCTs demonstrating improvements in oxygenation but not mortality or duration of ventilation with iNO administration for children with ARDS or hypoxemic respiratory failure.[129,144,145,147-151] A third small RCT on 32 children with ARDS examined the potential synergistic effects of prone positioning and iNO, demonstrating more sustained improvements in oxygenation with the combination of prone positioning and iNO over the first 24 hours of ventilation.[152] A multicenter trial has shown that iNO reduced the length of mechanical ventilation, mostly through lower use of ECMO.[153] Unlike the adult studies, there does not appear to be evidence of significant toxicity with iNO administration in pediatric ARDS.

Pediatric and adult evidence suggests iNO is probably best reserved for situations when refractory hypoxemia needs to be temporarily reversed (ie, as a bridge to extracorporeal support) or for patients with a true clinical indication such as documented pulmonary hypertension with right heart failure.[154]

Nonpulmonary Therapies

Prone Positioning

Physiologic Rationale

The best described and cited rationale for prone positioning of ARDS patients is that it improves regional V/Q matching due to a more uniform distribution of aerated lung, particularly in dorsal lung regions, thereby reducing physiologic dead space and improving oxygenation.[155,156] The effects of prone positioning on gas exchange are conventionally thought to be due to gravitational effects on the distribution of atelectasis and edema, as well as the effects of the weight of the heart and position of the dorsal diaphragm on the expansion of dorsal lung units.[157,158] Interestingly, prone positioning also appears to improve the cephalocaudal distribution of ventilation,

because the heart, mediastinal structures, and abdominal contents rest on the sternum. The prone position reduces regional differences in pleural pressure near the diaphragm that are normally present when upright or supine (Fig. 51.3).[158-161]

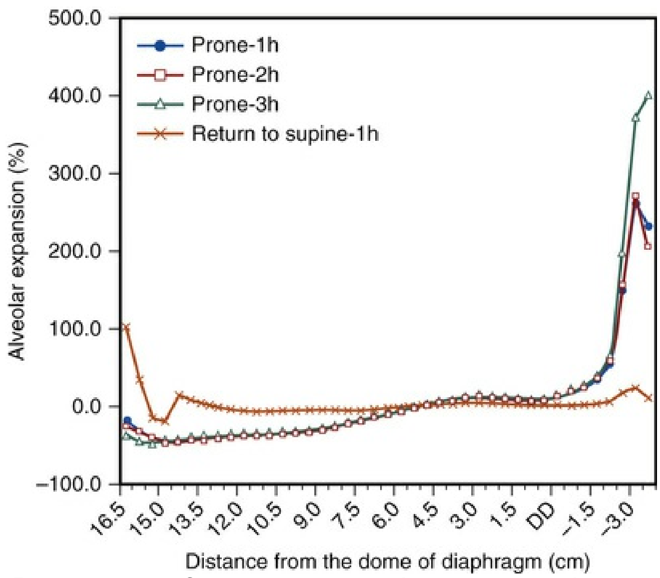

FIG. 51.3 Percentage of alveolar expansion along cephalocaudal axis. Zero line indicates cutoff between alveolar expansion and contraction. In prone group, alveolar expansion was observed in caudal regions and was most prominent in lung regions below diaphragmatic cupola. In upper lung, with 5 to 6 cm above the diaphragm as a turning point, alveolar contraction occurred. (Reproduced with permission Lee HJ, Im JG, Goo JM, et al. Acute lung injury: effects of prone positioning on cephalocaudal distribution of lung inflation—CT assessment in dogs. Radiology. 2005;234:151-161. Copyright © 2005 Radiological Society of North America.)

Prone positioning may also reduce inequalities in regional time constants and promote more effective alveolar ventilation to "slower" compartments.[162,163] These effects ultimately may influence lung stress and reduce the development of ventilator-induced lung injury.[164,165] When used in conjunction with high PEEP strategies currently recommended for ARDS, prone positioning may also increase alveolar recruitment and prevent cyclic recruitment/derecruitment and atelectrauma.[166] Minimizing derecruitment may be a physiologic explanation of why additional recruitment strategies such as HFOV sustain temporary improvements obtained by prone positioning.[167]

Patients with more compliant chest walls may have more benefit from prone positioning due to the reduction in chest wall compliance caused by limiting expansion of the sternum. This reduction in chest wall compliance, in addition to decreasing compression of lungs by the heart and decreasing the vertical pleural pressure gradient in the lungs, theoretically allows preferential distribution of ventilation to dorsal regions of lungs.[158] However, there is contradictory evidence for this mechanism and the overall effect of chest wall properties on the oxygenation response in prone positioning of ARDS patients.[168] It is also important to note that none of these studies were performed in children.

Other potential mechanisms for the beneficial effects of prone positioning include promoting airway secretion clearance[158] and lowering pulmonary artery pressure via

attenuation of hypoxic pulmonary vasoconstriction, although due to compromised preload, this effect may not directly translate into improvements in cardiac index.[169,170]

Preclinical or Adult Data

Animal models support the physiologic mechanisms detailed earlier. Adult data demonstrate that the gas exchange response to prone positioning is not universal and benefits only a subset of patients.[158,171,172] Moreover, the immediate improvement in oxygenation is inconsistently associated with a survival advantage in adults with ARDS.[173-175] However, prone positioning has been associated with improved survival in adults for whom dead space ventilation improved.[176,177]

There have been close to a dozen randomized controlled trials of prone positioning for ARDS in adults.[173,175,178-183] Two meta-analyses highlight significant heterogeneity in these trials, which may be due to duration of prone positioning, use of concurrent lung protective ventilation, tidal volume, hypoxemia severity, use of high frequency oscillatory ventilation, and duration of respiratory failure prior to prone positioning.[182,183] Nevertheless, both of these meta-analyses concluded that prone positioning affords a survival advantage for adults with ARDS, with the effect most pronounced in those who receive a longer duration of prone positioning, are managed with lung protective ventilation strategies with regard to PEEP and tidal volume, and have more severe lung injury and hypoxemia. However, when pooling the adverse events, those in the prone positioning group had a higher incidence of pressure ulcers, airway problems, and endotracheal tube obstruction.[182]

The Proning Severe ARDS Patients (PROSEVA) trial in adults is a major driver of the conclusions with regard to survival advantage with prone positioning.[179] Prone positioning was maintained for a minimum of 16 consecutive hours, and ventilator management was standardized with a lung protective ventilation protocol. Mortality was 32.8% in the supine group and 16% in the prone group at 28 days ($p < 0.001$). Unlike other studies, there were no increased adverse events in the prone group as compared with controls. The study suggests that prone positioning may benefit adults with severe ARDS when done by experienced providers, with a long consecutive duration of prone positioning and meticulous lung protective ventilation.

Pediatric Data

The results of the PROSEVA trial question existing data on prone positioning in children. Multiple uncontrolled trials and one randomized controlled trial on prone positioning have not demonstrated a survival advantage in children with ARDS.[184-188] The highest level of pediatric evidence comes from a multicenter randomized controlled trial in 2005,[189] which had detailed multidisciplinary protocols and guidelines for lung protective ventilation, sedation, extubation readiness, hemodynamic support, nutrition, and skin care.[190] This unblinded clinical trial was stopped early secondary to futility: There was no difference in the primary outcome of ventilator-free days or the secondary outcomes of mortality, time to recovery of lung injury, organ failure, cognitive impairment, and functional health. Most of the patients would now be considered to have moderate ARDS, and at the time study procedures began, nearly half of the children had PF ratios >150. Because of adult

data supporting more benefit from prone positioning for those with severe hypoxemia and repeated findings that strategies for lung protective ventilation may be important confounders on the relationship between prone positioning and outcome, the high use of high-frequency oscillatory ventilation in pediatrics may further confound these results.

Finally, although theory supports that children may have more pronounced benefits from prone positioning due to chest wall compliance, this benefit may be counteracted by less substantial compression of the lungs by the heart when supine as compared with adults. Future studies may benefit from the inclusion of measurements of transpulmonary pressure gradients as well as chest wall versus static lung compliance changes with prone positioning.

Monitoring

Pediatric patients with or at risk of PARDS should receive at least clinical monitoring of respiratory frequency, heart rate, continuous pulse oximetry, and noninvasive blood pressure.[191] Exhaled V_T should be measured at the endotracheal tube, especially in the smallest patients, or corrected for tubing compliance if measured at the ventilator. Exhaled V_T should likely be normalized to ideal body weight, although spinal deformities and contractures complicate measurement of height for calculation of “ideal” body weight. Inspiratory pressure (peak pressure in pressure modes and plateau pressure in volume modes), flow, and volume should be measured continuously. Continuous monitoring of SpO_2 (with titration of FiO_2 titrated to keep SpO_2 <97%), PEEP, and mean airway pressure (MAP) are essential to diagnose PARDS and monitor disease progression. Continuous capnography is important to determine the adequacy of support provided and monitor physiologic dead space, which is associated with disease severity. Arterial blood sampling may be required when the accuracy of noninvasive monitoring is unclear, and placement of arterial catheters may be indicated for hemodynamic assessments. Standard plain film chest x-rays are intermittently indicated for diagnosis, determining appropriate position of equipment, and diagnosing complications (pneumothorax), but it is not clear whether routine daily chest x-rays add value to the care of mechanically ventilated patients.

Noninvasive Support

Despite the widespread increased use of noninvasive support for pediatric and adult patients with acute respiratory failure, there are scant data to determine the utility of these modes of respiratory support for ARDS patients. Noninvasive support of ARDS patients has theoretic benefits, including avoidance of complications of intubation, preservation of spontaneous breathing and airway clearance, and reduced need for sedation. Noninvasive respiratory support can be considered for children with mild PARDS in a setting where trained and experienced staff can closely monitor for response to therapy and rapidly identify and treat deterioration.[192] Immunocompromised patients may particularly benefit from noninvasive respiratory support by avoiding the infectious risks of artificial airways. Uncontrolled descriptive pediatric studies suggest that it is feasible, and adult data

suggest that it is superior to medical therapy alone.

The severity of underlying disease and an early response to noninvasive support appear to be primary determinants of success. The presence of a second organ failure, requirement of >12 cm H_2O mean airway pressure, FiO_2 >0.6 or SF <190, high severity of illness scores (PELOD or PRISM), or moderate to severe ARDS suggest that noninvasive support will not be sufficient.[192-195] Once a patient is started on noninvasive support for respiratory failure, the patient must be closely monitored for evidence that she or he has responded. Failure to respond to noninvasive respiratory support within the first few hours has been associated with a need for intubation, higher complications rates at the time of intubation, and higher mortality in adults. Evidence that a patient has failed to respond to noninvasive respiratory support may include absence of a reduction in respiratory rate, ph <7.25 after 2 hour, increased oxygen requirement (FiO2 >80% after 1 hour), a decreased PaO_2/FiO_2 ratio or an SF <190, an increase of $PaCO_2$, or an altered level of consciousness.[192,195]

Extracorporeal Life Support

There are data from clinical trials of extracorporeal life support (ECLS) for neonates and adults with severe respiratory failure, but none in children. Data from the Extracorporeal Life Support Organization (ELSO) registry suggest that the average survival of >3500 children treated with ECLS for respiratory failure is 57% (51%–69%).[196] Improvements in diagnosis and risk stratification of PARDS will provide a means to perform better comparative effectiveness trials for ECLS versus conventional care. ECLS should be considered for children with severe PARDS from reversible causes in centers with clearly defined ECLS teams.[196]

Morbidity and Outcomes

Existing knowledge of the outcomes of PARDS is based on the application of the American-European Consensus Conference (AECC) criteria and suggests mortality rates of 15% to 50%.[197] Severity of hypoxemia, ventilator management, age, comorbidities (immunosuppression), and development of additional organ failures have been associated with mortality. However, it appears that the mortality of PARDS is decreasing, and little is known about the morbidity of survivors of PARDS.[197,198] Improvements in the recognition of PARDS should lead to a better understanding of the epidemiology. Future studies of the pulmonary, neurocognitive, and neuromuscular morbidities are needed in survivors of PARDS.

CHAPTER 52

Ventilator-Induced Lung Injury

Jean-Damien Ricard, Nicolas de Prost, Alexandre T. Rotta, Georges Saumon, Didier Dreyfuss

PEARLS

- Although essential to the support of patients with respiratory failure, mechanical ventilation can be associated with the development of pulmonary tissue injury, termed *ventilator-induced lung injury (VILI).*
- The concept of VILI has been elegantly tested in the research laboratory in both normal and diseased lungs, where the individual contribution of various factors such as tidal volume, positive end-expiratory pressure, and overall state of lung distention can be determined. Lung volume at the end of inspiration (ie, the overall degree of lung distension) probably is the main determinant of VILI severity.
- One must take the magnitude of the loss of aerated lung volume and alterations in lung mechanics into account to assess the risk of VILI.
- Experimental and clinical data support the idea that reasoned tidal volume reduction designed to prevent volutrauma can be advantageous in the management of these patients.

Mechanical ventilation is essential to the life support of patients with respiratory failure. Several potential drawbacks to mechanical ventilation were identified early in its history.[1] More recent experimental studies have shown that certain ventilation modalities may produce subtle tissue damage similar to that seen in early acute respiratory distress syndrome (ARDS) and termed *ventilator-induced lung injury (VILI).* This issue has received much attention in the clinical field.[2,3] This chapter describes the pathophysiologic events leading to VILI and places these observations into a clinical perspective of ventilatory management of patients with ARDS.

Evidence for Ventilator-Induced Lung Injury

Ventilation of Intact Lungs

High Lung Volume Ventilator-Induced Lung Injury

Webb and Tierney[4] found that pulmonary edema rapidly developed in rats subjected to 45 cm H_2O peak airway pressure ventilation. Edema severity and rate of development increased with peak airway pressure magnitude. It was later confirmed that such a ventilation modality produces endothelial and epithelial cell damage and lung capillary permeability changes that result in nonhydrostatic pulmonary edema.[5]

The respective roles of increased airway pressure and increased lung volume in this injury were clarified when mechanical ventilation at high and low tidal volume (V_T) were compared at identical (45 cm H_2O) peak airway pressures.[6] The injury was found only in rats subjected to high V_T and not in those undergoing ventilation at high airway pressure in which lung distention was limited by thoracoabdominal strapping (Fig. 52.1).[6] Furthermore, in animals undergoing ventilation at high V_T by negative external distending pressure, pulmonary edema still developed, confirming that excessive airway pressure is not the causal factor of this type of injury.[6] This VILI that depends mostly on end-inspiratory volume has been called volutrauma.[7,8] Several investigators reached the same conclusions in other species using different protocols,[9,10] confirming the fact that large tidal volumes are more critical than high intrathoracic pressures in the genesis of ventilator-induced lung edema in intact animals. The effects of gradual lung inflation on alveolar epithelial and pulmonary microvascular permeability to proteins were evaluated using a scintigraphic study in rats.[11] Two tracers were used,^{99m}Tc-albumin (in the alveolar instillate) and ^{111}In-transferrin (in the blood), which allowed for measuring both alveolar epithelial permeability (estimated from the rate at which ^{99m}Tc-albumin left the lungs) and microvascular permeability (measured from the accumulation of ^{111}In-transferrin in the lungs). Increasing lung tissue stretch by ventilation at high airway pressure immediately increased microvascular and alveolar epithelial permeability to proteins. The same end-inspiratory pressure threshold (between 20 and 25 cm H_2O) was observed for epithelial and endothelial permeability changes (Fig. 52.2). The existence of a lung distention threshold above which lung edema would develop was further confirmed in healthy pigs by Gattinoni and colleagues using the stress/strain approach. Indeed, when a lung strain (ie, the ratio between volume change and lung resting volume[12]) greater than 1.5 to 2 was achieved, corresponding to tidal volumes larger than 20 mL/kg in healthy animals,[13] a dramatic lung edema developed. This strain approach also allowed for the development of a unifying rule in various mammal species relating the time course of VILI with the lung strain applied.[14] Obviously, the lower the denominator (ie, low lung resting volume, the so-called baby lung effect), the greater will be the strain for a given lung inflation. In most of the definitions of strain, the numerator (ie, lung volume change) includes tidal volume plus positive end-expiratory pressure (PEEP) volume. However, it was previously suggested that the contribution of tidal volume and PEEP volume on lung strain are not equivalent (ie, *dynamic* and *static* lung strain). Indeed, Protti and colleagues showed in a pig model of VILI that the development of lung edema depended not only on the global strain applied but also on its components, large dynamic strains (ie, large tidal excursions) being more harmful than large static strains (ie, high PEEP and small V_T).[15]

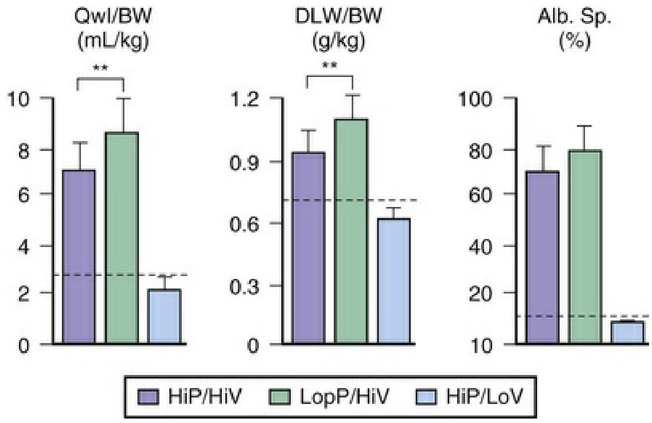

FIG. 52.1 Comparisons of the effects of high-pressure–high-volume ventilation *(HiP-HiV)* with those of negative inspiratory airway pressure high tidal volume ventilation (iron lung ventilation, *LoP-HiV)* and of high-pressure–low-volume ventilation (thoracoabdominal strapping, *HiP-LoV). Dotted lines* represent the upper 95% confidence limit for control values. See Fig. 53.4 for details on edema indices. Permeability edema occurred in both groups receiving high tidal volume ventilation. Animals undergoing ventilation with a high peak pressure and a normal tidal volume had no edema. *BW,* body weight; *DLW,* dry lung weight; *Qwl,* extravascular lung water. (From Dreyfuss D, Soler P, Basset G, et al. High inflation pressure pulmonary edema. Respective effects of high airway pressure, high tidal volume, and positive end-expiratory pressure. Am Rev Respir Dis. 1988;137:1159-1164.)

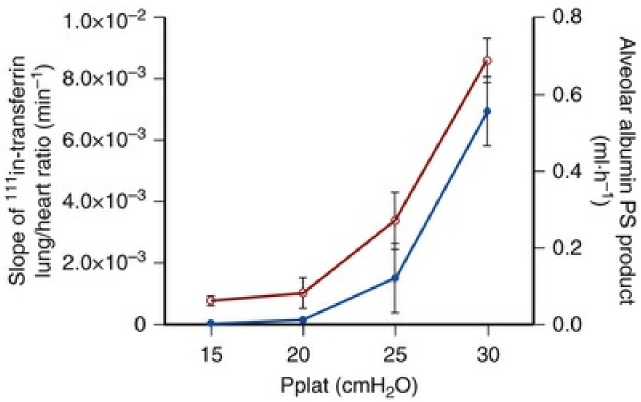

FIG. 52.2 Relationship between plateau pressure (*Pplat*) and ^{111}In-transferrin lung-to-heart ratio slope (an index of lung microvascular permeability; *left axis, open circles*) and alveolar ^{99m}Tc-albumin permeability-surface area product (an index of alveolar epithelium permeability; *right axis, full circles*) in mechanically ventilated rats. Both indexes dramatically increased for plateau pressures composed between 20 and 25 cm H_2O. (From de Prost N, Dreyfuss D, Saumon G. Evaluation of two-way protein fluxes across the alveolo-capillary membrane by scintigraphy in rats: effect of lung inflation. J Appl Physiol. 2007;102:794-802.)

Pediatric experimental models of VILI showed consistent results from those obtained with older animals. For instance, lung injury developed in infant mice with healthy lungs when V_T's greater than 20 mL/kg were used[16] and, using a two-hit model of injurious mechanical ventilation and lipopolysaccharide (LPS) exposure,

Roth-Kleiner and associates showed that there was a synergistic response on cytokines production and histologic lesions in animals receiving both insults.[17] Several studies compared the effects of injurious mechanical ventilation strategies between pediatric and adult models of VILI and revealed that there was an age-related susceptibility to VILI, the former being less sensitive than the latter.[18] The factors accounting for these differences are not totally understood; the fact that the functional residual capacity-to-body weight ratio is greater in the immature than in the mature lung implies that for the same V_T applied in mL/kg of body weight, pediatric lungs would in fact experience a lower strain than adult lungs.[18] Nevertheless, even after adjusting V_T's for baseline total lung capacity, Kornecki and coworkers found greater susceptibility to an injurious mechanical ventilation strategy in adult than in pediatric rats,[19] suggesting less susceptibility of pediatric patients to VILI and making it difficult to directly extrapolate the results obtained from large randomized-controlled trials conducted in the adult population to the pediatric population.[18]

Low Lung Volume Ventilator-Induced Lung Injury

Unlike volutrauma, ventilation at low lung volumes does not seem to injure healthy lungs. Intact animals tolerate mechanical ventilation with physiologic V_T and low levels of PEEP for prolonged periods of time without any apparent damage. Taskar and colleagues[20] have shown that the repetitive collapse and reopening of terminal units during 1 hour of mechanical ventilation did not result in appreciable lung damage, although it did alter gas exchange and reduce compliance, as does spontaneous (low V_T) ventilation under deep anesthesia.

Ventilation of Damaged Lungs

High-Volume Lung Injury

Several investigators have evaluated the effect of overdistention on damaged lungs. These studies consistently demonstrated the increased susceptibility of diseased lungs to the detrimental effects of some modalities of mechanical ventilation.

Hernandez and colleagues[21] compared the effects of oleic acid alone, mechanical ventilation alone, and their combination on lung capillary filtration coefficient and wet-to-dry lung weight ratio in young rabbits. Filtration coefficient and wet-to-dry weight were not significantly affected by low doses of oleic acid or by mechanical ventilation at a peak inspiratory pressure of 25 cm H_2O for 15 minutes. However, the filtration coefficient as well as the wet-to-dry weight ratio increased significantly when oleic acid injury was followed by mechanical ventilation at these pressures, suggesting that ventilation at high volume and pressure might favor VILI in abnormal isolated lungs and that it might occur at lower airway pressure than in the normal lung. Whether this could also occur in lungs in situ was investigated by comparing the effects of different modalities of mechanical ventilation in rats with α-naphthylthiourea (ANTU)-injured lungs[22] (Fig. 52.3). ANTU infusion alone caused moderate permeability pulmonary edema. Mechanical ventilation alone resulted in a permeability edema of severity related to magnitude of V_T. Strikingly, lungs of animals injured by ANTU had more edema than predicted when they underwent

ventilation with a high V_T (45 mL/kg body weight), indicating that the two insults acted in synergy. Even slight lung alterations, such as those produced by spontaneous ventilation during prolonged anesthesia (which inactivates surfactant and promotes focal atelectasis[23,24]), are sufficient to exacerbate the harmful effects of high-volume ventilation.[22] The extent to which lung mechanical properties are altered prior to ventilation is a key factor in this synergy. The amount of pulmonary edema produced by high-volume mechanical ventilation in animals given ANTU, or after prolonged anesthesia, was inversely proportional to respiratory system compliance measured at the beginning of high-volume mechanical ventilation.[22] Thus the more severe the lung abnormalities were before ventilation, the more severe was the VILI.

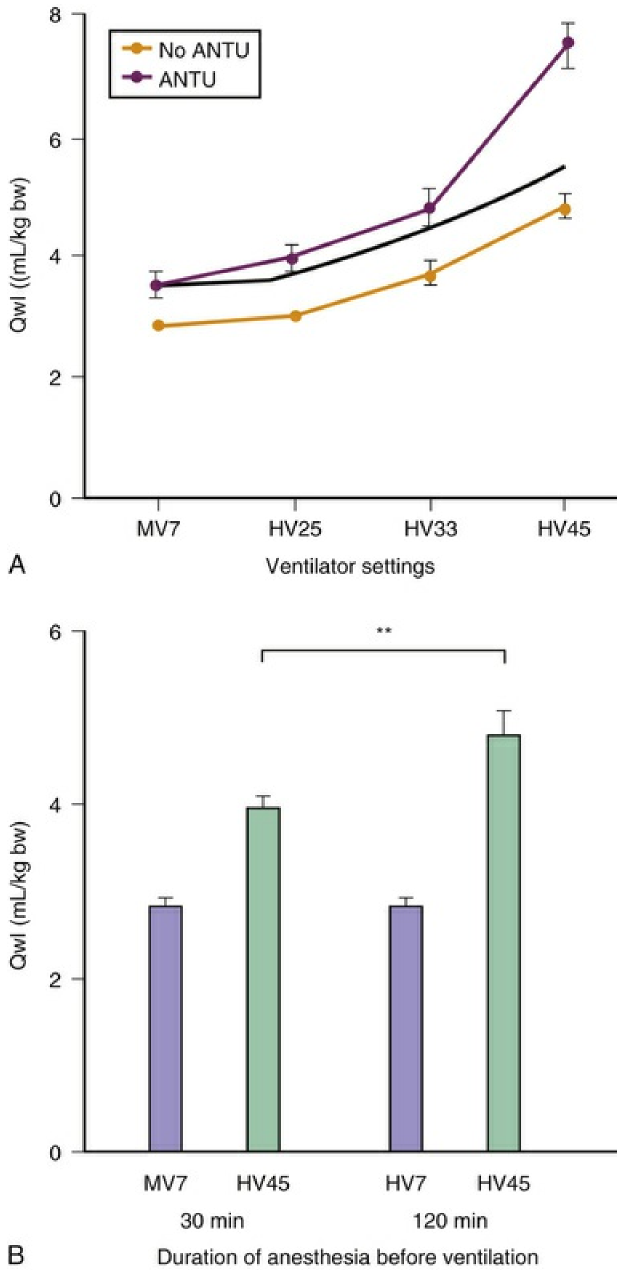

FIG. 52.3 Interaction between previous lung alterations and mechanical ventilation on pulmonary edema. (A) Effect of previous toxic lung injury.

Extravascular lung water *(Qwl)* after mechanical ventilation in normal rats *(orange circles)* and in rats with mild lung injury produced by α-naphthylthiourea (ANTU) *(purple circles).* Tidal volume (V_T) varied from 7 to 45 mL/kg body weight *(bw) Black line* represents the Qwl value expected for the aggravating effect of ANTU on ventilation edema assuming additive. ANTU did not potentiate the effect of ventilation with V_T up to 33 mL/kg bw. In contrast, ventilation at 45 mL/kg bw V_T resulted in an increase in edema that greatly exceeded additivity, indicating synergy between the two insults. (B) Effect of lung functional alteration by prolonged anesthesia. Intact rats were anesthetized and breathed spontaneously for 30 or 120 minutes prior to mechanical ventilation with 7 mL/kg bw *(open bars)* or 45 mL/kg bw *(shaded bars)* V_T in intact rats. Qwl of animals that underwent ventilation with a high V_T was significantly higher than in those that underwent ventilation with a normal V_T. Qwl was not affected by the duration of anesthesia in animals that underwent ventilation with a normal V_T. In contrast, 120 minutes of anesthesia before high V_T ventilation resulted in a larger increase in Qwl than did 30 minutes of anesthesia. $^{**}p < .01$. (From Dreyfuss D, Soler P, Saumon GL. Mechanical ventilation-induced pulmonary edema. Interaction with previous lung alterations. Am J Respir Crit Care Med. 1995;151:1568-1575.)

The reason for this synergy requires clarification. The presence of zones of alveolar edema in animals given this harmful ventilation was the most evident difference from those that underwent ventilation with lower, less harmful V_T.[22] Because alveolar flooding reduced the number of alveoli available for ventilation, they were more prone to overinflation, more vulnerable, and at greater risk of alveolar flooding. This in turn would further reduce aerated lung volume and result in positive feedback. Thus, uneven distribution of ventilation during acute lung injury[25] favors regional overinflation and injury. To substantiate this phenomenon, rats underwent ventilation with V_T of up to 33 mL/kg after alveolar flooding by instillation of saline solution into the trachea. Flooding with saline solution did not significantly affect microvascular permeability when V_T was low. As expected, capillary permeability alterations were more important in animals that experienced alveolar flooding than in intact animals that underwent ventilation at high V_T. Correlations also were found among end-inspiratory (plateau) airway pressure, the pressure at the “lower inflection point” on the pressure-volume (PV) curve, and the capillary permeability changes found in animals that experienced alveolar flooding and underwent ventilation with at high V_T (Fig. 52.4).[26] Thus the changes in capillary permeability caused by lung overinflation are more severe in poorly recruitable (and less compliant) lungs.

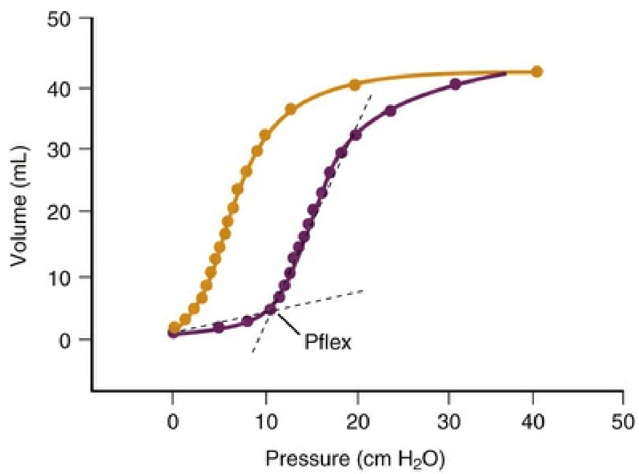

FIG. 52.4 Static volume-pressure relationship for the total respiratory system of a surfactant-depleted juvenile rabbit. *Pflex* indicates the lower inflexion point.

Low-Volume Lung Injury

An increase in trapped-gas volume during pulmonary edema and acute lung injury probably occurs because of airway closure and is worsened by impaired surfactant function.[27] Under such conditions, the slope of the inspiratory limb of the respiratory system PV curve often displays a sharp increase at low lung volume. This change reflects the sudden and massive opening of units previously excluded from ventilation and has been termed the *lower inflection point.* This phenomenon often has a dramatic effect on arterial oxygenation, because setting PEEP above the pressure at this inflection point often decreases shunt and increases PaO_2.[28-31]

The possibility that pulmonary dysfunction may be aggravated if this inflection point lies within the V_T has been a focus of attention. Studies performed on surfactant-depleted lungs ventilated at various levels of PEEP suggest that repeated closure and reopening of terminal units can cause lung injury.[32-34] Indeed, during volume-controlled ventilation, lung compliance fell over time. However, when PEEP was adjusted to be either above or below the lower inflection point of the inspiratory limb of the PV curve, arterial PaO_2 was better preserved and less hyaline membrane formation occurred in the high-PEEP group.[32,33] Muscedere and colleagues[35] reported similar results in isolated, unperfused rabbit lungs lavaged with saline solution and ventilated with a low (5 to 6 mL/kg) V_T and with a PEEP set below or above the inflection point. However, Sohma and colleagues[34] did not find this injury in vivo in rabbits whose lungs had been injured with hydrochloric acid,[34] and Martynowicz and coworkers[36] have questioned the existence of the repetitive collapse-reexpansion phenomenon during tidal ventilation using the parenchymal marker technique for studying regional lung expansion in oleic acid–injured dog lungs. Their findings therefore did not support the hypothesis that a more important gravitational gradient during VILI produces atelectasis by compression of the dependent lung, cyclic recruitment and collapse, and ultimately shear stress injury.[36] They proposed that the displacement of air-liquid interfaces along the tracheobronchial tree would cause the lower inflection point on the PV curve and speculated that this would reflect the mechanics of partially fluid-filled alveoli with constant surface tension

and not the abrupt opening of airways or atelectatic parenchyma.[37] It therefore remains unsettled whether injury caused by the repetitive reopening of collapsed terminal units and the protective effect of PEEP is restricted to the peculiar situation of surfactant depletion by bronchoalveolar lavage. In the clinical arena, the negative results of three randomized controlled trials comparing higher to lower PEEP levels[2,38,39] cast doubt on the clinical existence of repetitive opening and closing lung injury.

Roles of Tidal Volume, Positive End-Expiratory Pressure, and Overall Lung Distention

The influence of PEEP on acute lung injury (and more specifically on ventilator-induced pulmonary edema) must be studied in the context of the level of V_T. Indeed, PEEP increases functional residual capacity (FRC) and recruits the lung but also increases end-inspiratory volume when V_T is kept constant, thus possibly favoring overinflation. PEEP application also may depress hemodynamics and affect lung fluid balance. Therefore close analysis of the numerous studies that have been done to clarify the relationships between PEEP, oxygenation, and extravascular lung water accumulation during hydrostatic or permeability type edema must take into account the experimental approach used, that is, intact animals or isolated lungs (for which lung water content will differ), and whether or not V_T is reduced (thus increasing or not increasing end-inspiratory lung volume).

Effects of Positive End-Expiratory Pressure When Tidal Volume Is Kept Constant

Application of PEEP may result in lung overinflation if it is followed by a significant change in FRC because of the increase in end-inspiratory volume. Overinflation will affect preferentially the more distensible areas that receive the bulk of ventilation, which may explain the lack of reduction or even the worsening of edema reported following PEEP application in most experiments.[40] PEEP does not affect the severity of hydrostatic[41] or permeability[41,42] edema in intact animals, although it improves oxygenation[41] because of the recruitment of flooded alveoli (Fig. 52.5). In isolated ventilated-perfused lungs, PEEP rather aggravates edema fluid accumulation[43] (Fig. 52.6). Thus when V_T is left unchanged, increasing FRC with PEEP affects edema differently in isolated lungs or in intact animals. In the latter, the lack of effect of PEEP depends on the balance between PEEP-induced increase in end-inspiratory lung volume, which decreases interstitial pressure and increases filtration pressure in extra-alveolar vessels, and the hemodynamic depression due to elevated intrathoracic pressure that, in the opposite, decreases filtration pressure. In contrast, preservation of perfusion rate in isolated-perfused lungs favors edema formation.[43]

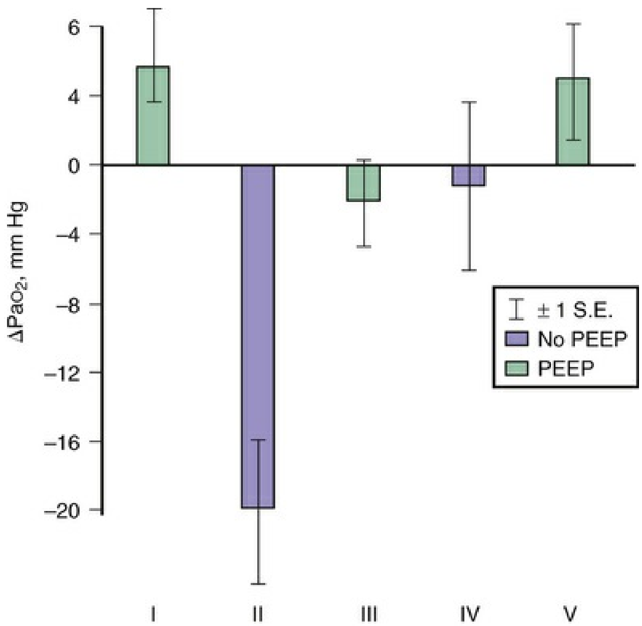

FIG. 52.5 Change in arterial oxygen tension (ΔPaO_2, mm Hg) during the 1-hour period between the initial and final measurements for groups I (control), II, and III (severe hydrostatic pulmonary edema, without and with positive end-expiratory pressure [PEEP], respectively) and IV and V (moderate pulmonary edema, without and with PEEP, respectively). The difference between ΔPaO_2 for groups II and III is significant ($p < .01$). (From Hopewell PC, Murray JF. Effects of continuous positive-pressure ventilation in experimental pulmonary edema. J Appl Physiol. 1976;40:568-574.)

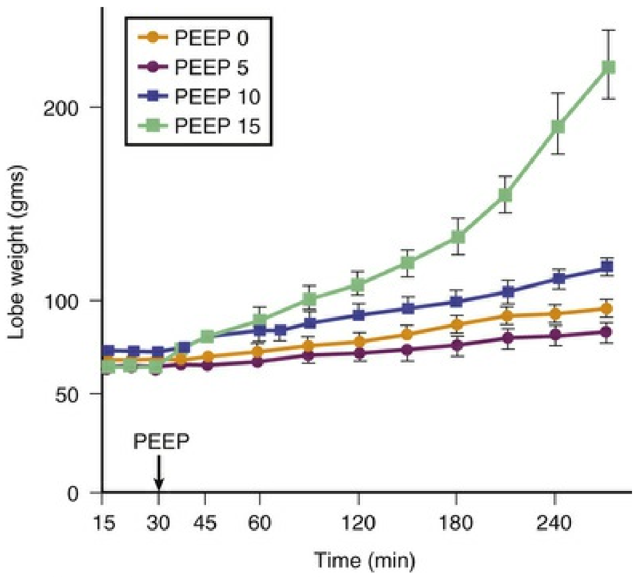

FIG. 52.6 Effect of three levels of positive end-expiratory pressure (PEEP) on water accumulation in hydrochloric acid–injured ventilated-perfused dog pulmonary lobes. The highest PEEP resulted in a further increase in pulmonary edema. (From Toung T, Saharia P, Permutt S, et al. Aspiration pneumonia: beneficial and harmful effects of positive end-expiratory pressure. Surgery. 1977;82:279-283.)

Effects of Positive End-Expiratory Pressure When Tidal Volume Is Reduced

Edema is less severe during high-volume ventilation (even though FRC is increased by PEEP) when end-inspiratory lung volume is kept constant by decreasing V_T (Fig. 52.7). Webb and Tierney[4] showed that less edema developed during ventilation with 45 cm H_2O peak airway pressure when 10 cm H_2O PEEP was applied. The authors attributed this benefit of PEEP to the preservation of surfactant activity. It was later shown that, although PEEP decreased the amount of edema, it did not prevent alteration of capillary permeability.[6] However, animals undergoing ventilation with PEEP had no alveolar damage in contrast with those that underwent ventilation without PEEP. The only cellular alterations found in animals that underwent ventilation with PEEP consisted of capillary endothelial blebs.[6] No satisfactory explanation has been found for this preservation of the epithelial layer. It may be that PEEP prevented fluid movement in terminal units, thereby decreasing shear stress at this level. The hemodynamic alterations induced by PEEP probably play an important role in lessening the severity of edema. Application of PEEP produces an increase in mean intrathoracic pressure that adversely affects cardiac output.[44,45] For example, in rats subjected to high peak airway pressure and 10 cm H_2O PEEP, edema was more severe when the hemodynamic alterations induced by PEEP were corrected with dopamine infusion.[46] The amount of extravascular lung water was correlated with systemic blood pressure, suggesting that restoration of cardiac output increased filtration pressure and was responsible for aggravation of edema. The reduction of edema and of the severity of cellular damage by PEEP during ventilation-induced pulmonary edema may be linked to reduced tissue stress by decreasing volume-pressure excursion, movement of foam in distal airways, preservation of surfactant activity, and a decrease in capillary filtration.

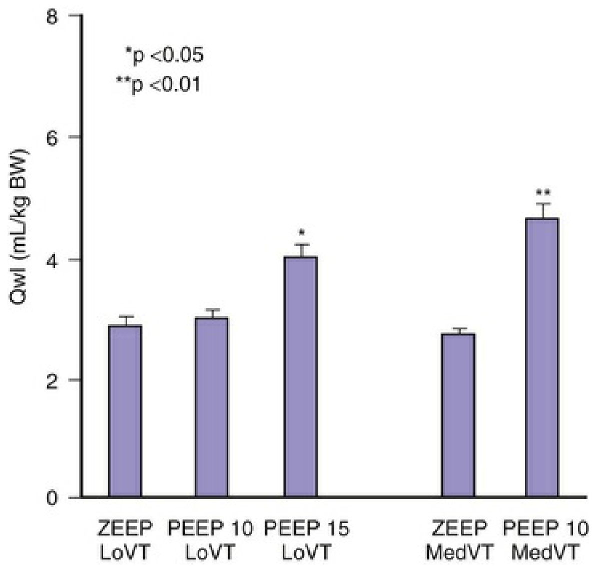

FIG. 52.7 Effect of increasing positive end-expiratory pressure (PEEP) from 0 to 15 cm H_2O during ventilation with two different tidal volume (V_T) values (7 mL/kg body weight *[BW]*: LoV_T and 14 mL/kg BW: $MedV_T$). Pulmonary edema (as evaluated by increases in extravascular lung water

[Qwl]) occurred when PEEP was increased. PEEP required to produce edema varied with V_T: 15 cm H_2O PEEP during ventilation with low V_T and 10 cm H_2O PEEP during ventilation with moderately increased V_T. *p <.05; **p <.01 versus zero end-expiratory pressure (ZEEP) and the same V_T. (From Dreyfuss D, Saumon G. Role of tidal volume, FRC, and end-inspiratory volume in the development of pulmonary edema following mechanical ventilation. Am Rev Respir Dis. 1993;148:1194-1203.)

Possible Mechanisms of Ventilator-Induced Lung Injury

It is now clear that ventilation-induced pulmonary edema is essentially the result of severe changes in the permeability of the alveolar-capillary barrier. Small increases in filtration pressure may combine with altered permeability to aggravate edema.

Ventilation may damage lungs by two different mechanisms, and the severity of damage depends on both intensity and duration of the insult. A rapidly occurring and severe permeability pulmonary edema may be produced in small animals as a consequence of acute lung stretch. This edema does not appear to require the involvement of inflammatory cells or secretion of mediators and can occur within a few minutes. Edema develops more slowly in larger animals for the same plateau pressure, rendering the situation more complex. A low lung volume injury may contribute its own effects to high end-inspiratory volume damage. Further, ventilation without PEEP may reduce aerated lung volume and gradually worsen mechanical nonuniformity. This lung inhomogeneity will in turn promote overinflation of the more compliant and probably healthier zones, leading to positive feedback aggravation. In addition, when lung lesions develop slowly, inflammatory pathways have enough time to be activated and may participate in tissue injury (Fig. 52.8).

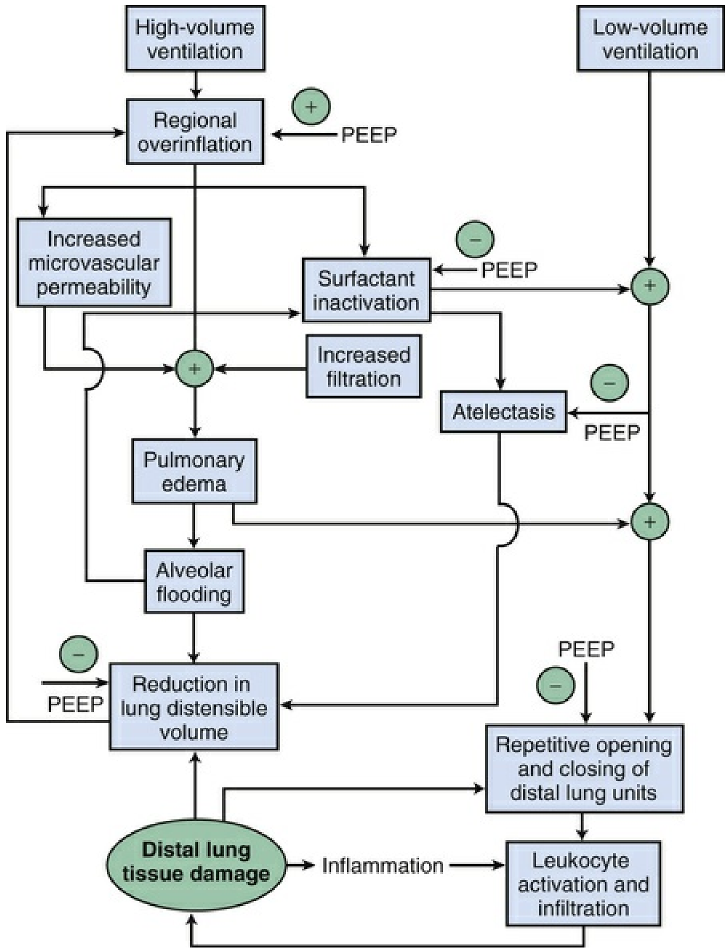

FIG. 52.8 Flow diagram summarizing the contributors to mechanical ventilation–induced lung injury. Positive end-expiratory pressure (PEEP) generally opposes injury or edema formation *(minus sign)* except when it contributes to overinflation *(plus sign)*. (From Dreyfuss D, Saumon G. Ventilator-induced lung injury: lessons from experimental studies. Am J Respir Crit Care Med. 1998;157:294-323.)

Mechanisms of Increased Vascular Transmural Pressure

Increased fluid filtration may occur at both extra-alveolar[47,48] and alveolar[49-51] sites during mechanical ventilation. Increased transmural pressure in extraalveolar vessels results from the increase in lung volume, and the decrease in perivascular interstitial pressure is the consequence of lung stretch.[45,52,53] Increased filtration across alveolar microvessels also may be promoted by the surfactant inactivation[4,49] that accompanies ventilation at high V_T or because of the presence of plasma proteins (such as fibrinogen and albumin) in airspaces.

Mechanisms of Altered Permeability

Although capillary permeability alterations are obvious and may be severe during ventilator-induced edema, the underlying mechanisms are not fully understood and may vary according to the extent and duration of lung overdistention.

Effects of Surfactant Inactivation

In addition to its effects on fluid filtration, surfactant inactivation and elevated alveolar surface tension may increase alveolar epithelial permeability to small solutes. Surfactant inactivation by detergent aerosolization increases diethylenetriaminepentaacetic acid (DTPA) clearance in rabbits[54] and dogs.[55] This effect has been ascribed to the ventilation inhomogeneities and regional overexpansion that result from uneven inactivation of surfactant and maldistribution of lung mechanical properties rather than to the elimination of peculiar barrier properties of surfactant.[55] The effects of surfactant inactivation and large V_T ventilation on alveolocapillary permeability (as assessed by pulmonary DTPA clearance) are additive.[56] Endothelial permeability may be altered because the increased surface tension due to surfactant inactivation augments radial traction on pulmonary microvessels.[49]

Participation of Inflammatory Cells and Mediators

Role of Inflammatory Cells

The endothelial cell disruption observed during overinflation edema in small animals may allow direct contact between polymorphonuclear cells and the basement membrane. This contact may promote leukocyte sequestration. A striking feature of the VILI that occurs after several hours is the infiltration of inflammatory cells into the interstitial and alveolar spaces. In one of the earliest studies on this subject, Woo and Hedley-White[57] observed that overinflation produced edema in open-chest dogs and that leukocytes accumulated in the vasculature and macrophages in the alveoli. Further studies have confirmed these results[58] and have shown that high transpulmonary pressure increased the transit time of leukocytes in the lungs of rabbits.[59] Conversely, when animals are depleted of neutrophils, high-volume pulmonary edema is less severe than in nondepleted animals.[60]

Role of Inflammatory Mediators (Biotrauma Hypothesis)

Tremblay and colleagues[61] examined the effects of different ventilatory strategies on the level of several cytokines in bronchoalveolar lavage fluid of isolated rat lungs ventilated with different end-expiratory pressures and V_T. High V_T ventilation (40 mL/kg) with zero end-expiratory pressure resulted in considerable increases in tumor necrosis factor (TNF)-α, interleukin (IL)-1β and IL-6, and macrophage inflammatory protein (MIP)-2 (Fig. 52.9). Although these findings have been inconstantly replicated in animals with healthy lungs and it remains unclear whether injurious ventilator settings can result in primary production of pro-inflammatory cytokines in the lungs,[62,63] it will do so when combined with another aggression (ie, the two-hit theory), such as hemorrhagic shock and resuscitation[64] or mesenteric ischemia-reperfusion.[65] The biotrauma hypothesis forms the rationale for the attempts to modulate pharmacologically the imbalance between lung pro- and antiinflammatory mediators during VILI.

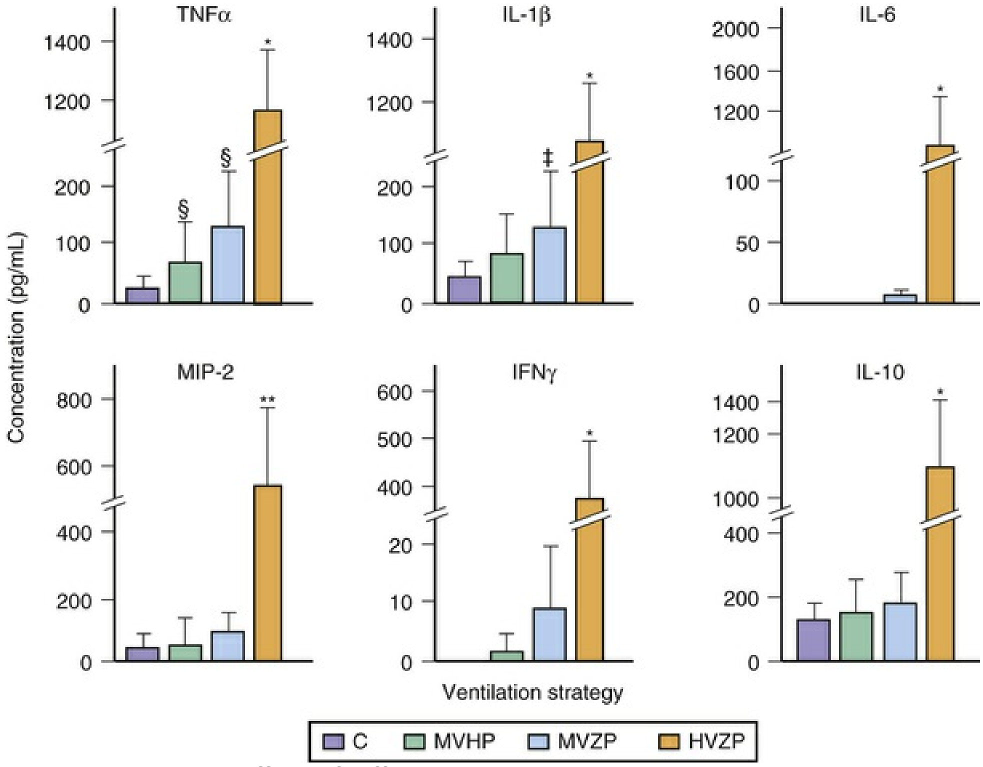

FIG. 52.9 Effect of different ventilatory strategies on cytokine concentrations in lung lavage of isolated unperfused rat lungs. Four ventilator settings were used: controls (*C*, normal tidal volume [V_T]), moderate V_T + high positive end-expiratory pressure (PEEP) *(MVHP)*, moderate V_T + zero PEEP *(MVZP)*, and high V_T + zero PEEP *(HVZP)* resulting in the same end-inspiratory distention as MVHP. Major increases in cytokine concentrations were observed with HVZP. *IFN,* interferon; *IL,* interleukin; *MIP,* macrophage inflammatory protein; *TNF,* tumor necrosis factor. (From Tremblay L, Valenza F, Ribeiro SP, et al. Injurious ventilatory strategies increase cytokines and c-fos m-RNA expression in an isolated rat lung model. J Clin Invest. 1997;99:944-952.)

In addition to increasing the amount of cytokines in the lung, it has been suspected that overinflation during mechanical ventilation may promote the release of cytokines[66,67] or bacteria[68,69] into the blood, thus giving a causative role for mechanical ventilation in multiorgan dysfunction.[70] However, this hypothesis remains to be proved.[71]

New Insights in Ventilator-Induced Lung Injury

Cellular Response to Mechanical Strain and Pharmacologic Interventions

Parker and colleagues[72] studied the different signal transduction pathways that may be involved in the microvascular permeability increases observed during experimental VILI. They found that gadolinium, which blocks stretch-activated nonselective cation channels, annulled the increases in vascular permeability induced by high airway pressure.[73] The authors concluded that stretch-activated cation channels might initiate the increase in permeability induced by mechanical

ventilation through increases in intracellular Ca^{2+} concentration. Such results suggested that the increase in microvascular permeability may not simply be a passive physical phenomenon (a *stress failure*[74,75]) but may at least in part be the result of biochemical reactions.

Numerous cell signaling pathways have indeed been shown to be involved in the pathophysiology of VILI. Several pharmacologic interventions have been tested, including (1) attempts to modulate the microvascular permeability using blockers of stretch-activated cation channels,[73] beta-adrenergic agonists,[76] inhibitors of phosphotyrosine kinase,[77] or reducing myosin light chain phosphorylation with adrenomedullin[78]; (2) attempts to modulate the imbalance between pro- and antiinflammatory mediators in the lung (eg, administration of anti–TNF-α antibody[79-81] and inhibition of MIP-2 activity,[82,83] which reduced neutrophilic infiltration and lung injury); and (3) attempts to modulate hormonal and metabolic pathways. For instance, inhibition of the renin-angiotensin system[84,85] and pretreatment with atorvastatin or simvastatin[86,87] decreased alveolar-capillary barrier permeability and lung inflammation in experimental models of VILI. Nevertheless, none of those pharmacologic interventions has proved beneficial for the prevention and treatment of VILI in patients. Although it is probably illusory to believe that a single pharmacologic intervention might be beneficial in patients, the description of those pathways illustrates the complexity of the cellular mechanisms involved in VILI.

Influence of Carbon Dioxide Tension on Ventilator-Induced Lung Injury

Deleterious effects of hypocapnia have been extensively reviewed.[88] However, it is important to note that, in addition to detrimental effects of hypocapnia[89] and hypercapnia[90] on ischemia-reperfusion lung injury, experimental studies suggest that hypercapnia may protect from the acute increase in capillary permeability caused by overinflation[91] and from inflammation during VILI.[92]

Strategies to Reduce Ventilator-Induced Lung Injury: Use of the Pressure-Volume Curve and Analysis of the Mechanics of the Respiratory System

The ARDS network trial[93] has undisputedly shown that reducing V_T from 12 mL/kg to 6 mL/kg resulted in a 22% reduction in mortality rate (Fig. 52.10). By protocol, the same reduction of V_T was applied to all patients allocated to the low V_T group. However, it has repeatedly been shown that pressures and the volumes considered safe for some patients with ARDS may cause lung overdistention in others.[94-97] Conversely, arbitrary settings may result in an unnecessary reduction in V_T, which a meta-analysis has suggested as being potentially harmful.[98]

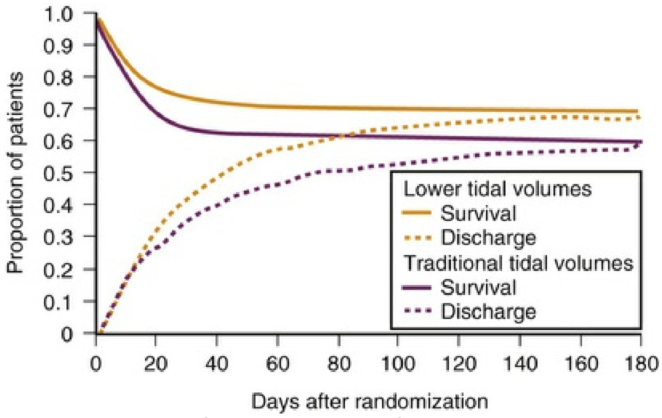

FIG. 52.10 Probability of survival and of being discharged home and breathing without assistance during the first 180 days after randomization in patients with acute lung injury and acute respiratory distress syndrome. (From The Acute Respiratory Distress Syndrome Network. Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. N Engl J Med. 2000;342:1301-1308.)

Taking the presence and value of a lower inflection point (LIP) on the pressure-volume curve into account when setting the level of PEEP may lessen VILI in some[32,33,35] but not all instances.[34] The concept on lung protection against VILI with the setting of a PEEP level above the LIP, however, relies on a putative stabilizing effect of PEEP that would reduce the repetitive opening and closing of distal lung units. As discussed earlier, serious criticisms have been raised against this opening and closing theory,[99] casting doubt on the usefulness of measuring LIP to prevent VILI.

The overall degree of lung distention resulting from the settings of both PEEP and tidal volume is a fundamental determinant of VILI. Although the exact physiologic significance of an upper inflection point (UIP) is debated, it may indicate lung overstretching. Ventilation that takes place above the UIP was found to be markedly deleterious.[100] Thus, determination of the volume at which the UIP is observed may help reduce the risk of VILI, because it indicates the maximum stretch that the lung can sustain without noticeable damage.[100] Analysis of the airway pressure-time curve during mechanical ventilation has also proved useful in determining the stress applied to lungs. Indeed, an upward concavity of the pressure-time curve suggests that compliance decreases as tidal volume is delivered, with resulting high-volume stress.[101] Such a ventilation pattern was associated with histologic lung injury in an isolated, nonperfused, lavage model of acute lung injury[101] and with overdistention, as attested by CT-scan analysis of the lungs of intact animals with saline lavage-induced lung injury.[102] The same group of authors demonstrated that in patients with ARDS, a ventilation strategy achieving a stress index greater than 1.05 (ie, the shape of the pressure-time curve demonstrating an upward concavity) had a negative predictive value of 0.86 for the presence of tidal hyperinflation, as assessed by chest CT scan.[103]

Amato and colleagues proposed using the driving pressure, which is the tidal volume normalized by the compliance of the respiratory system, to reconcile discrepant findings from clinical studies reporting conflicting responses from the manipulation of tidal volume, plateau pressure, and PEEP.[2,38,39,93,104,105] Reanalyzing the results of previously published clinical studies, using a mediation analysis of

individual data from 3562 patients, they concluded that among the ventilator parameters studied, the driving pressure was most closely associated with mortality, with each 1 SD increment (7 cm H_2O) being associated with a relative risk of 1.41.[106] Although clinical evidence is still lacking to ascertain that ventilation strategies aiming at reducing the driving pressure would improve outcomes of patients with ARDS, this parameter might help explain the negative results of these studies comparing higher versus lower PEEP levels.[2,38,39]

Strategies to Reduce Ventilator-Induced Lung Injury: Mechanical Measures

Prone position was shown to be lung protective in experimental models because it favors a more homogeneous distribution of transpulmonary pressure gradient,[107] it increases lung recruitment of collapsed areas, thereby lowering lung strain,[108,109] and it improves gas exchanges through regional perfusion alterations.[110] As compared to supine position, prone position homogenized the distribution of lung injury in dogs with normal lungs subjected to injurious ventilation[111] and lessened the histologic lesions in dogs with previously injured lungs and similar ventilator settings.[112] These benefits have led to the realization of clinical studies assessing the impact of prone position in ARDS patients. Three randomized controlled trials in ARDS showed no benefit to prone positioning on 28-day mortality and ventilator-free days in spite of significant improvement in oxygenation.[113-115] However, a randomized-controlled trial including 466 patients with ARDS and a PaO_2/FiO_2 ratio <150 mm Hg who were randomized to receive a conventional ventilation strategy alone or associated with early and protracted (ie, 16 hours a day) prone position showed a significant reduction in mortality at day 28 (16% versus 33%, $p < 0.001$).[116] This dramatic reduction in mortality is ascribed to a reduction of VILI, and prone position is now believed to be a crucial aspect of management of patients with severe (ie, PaO_2/FiO_2 ratio <150 mm Hg) ARDS.

The effect of surfactant administration was assessed in experimental models of VILI demonstrating that (1) the preventive intratracheal administration of exogenous surfactant reduced impairment of lung mechanics, oxygenation, and alveolar permeability in rats subjected to an injurious ventilation strategy[117] and (2) that a pretreatment with surfactant altered the systemic spread of lung-borne TNF-α of LPS-exposed[118] but not of previously healthy rats.[119] Yet the results of the clinical trials that tested the effects of surfactant administration in ARDS patients were disappointing: Aerosolized[120] or tracheally instilled[121] surfactant had no effect on survival and lung mechanics in an adult population of ARDS patients in spite of an effect on oxygenation during the 24 hours following administration in one study.[121] These negative results might be attributed to both the types of surfactant used and administration modalities. As a matter of fact, in pediatric patients with acute lung injury (premature infants being excluded), and as compared to placebo, the intratracheal administration of a natural surfactant (calfactant) was associated with reduced mortality (19.5% versus 36%) and improved lung mechanics and oxygenation, but there were no differences in ventilator-free days.[122]
